The Chairman said that, in the paper which Dr. Anthony had favoured them by reading at their last meeting, he had remarked that a stop placed in front of a lens caused the aberration to be of such a nature that straight parallel lines were rendered as curved towards each other, and produced the so-called "barrel" shape; while, if the stop were placed behind the lens, the rays crossed after passing through, and produced an aberration in an opposite direction called "pin-cushion," the lines being bowed from each other. He should like to know how the Doctor proposed to remedy this?

Dr. Anthony said that Dallmeyer's triplet lens was constructed with a negative lens between the others, for the purpose of avoiding both the "pin-cushion" and "barrel" distortions; but, to reduce the distortion to a minimum in a single lens, the object was to cause the eccentric pencils to fall upon the circumference, instead of the direct or central pencils, never forgetting that in placing the stop, and regulating the aperture of that stop, the photographer had to deal with a cone of light and not with parallel rays.

The Chairman said that many opticians made the stops in their lenses immovable. He had himself a landscape lens in which the stop was fixed.

Dr. Anthony said he had, a few days ago, been speaking on that subject with Mr. Ackland, who acknowledged to him that in every case the stop ought to be movable. Makers, however, placed the stop in what they thought the best average position; as, if moveable, amateurs would be almost certain to place them in the worst position possible, and then write angry letters to say that the lenses sold to them would not work. He believed that for those who wished to work with care, and who had a knowledge of the subject, the stop ought to be moveable, both in landscape and portrait lenses. Since the meeting of March 26th, he (Dr. Anthony), with the assistance of Mr. Brown (the Honorary Secretary of the Society), had made a series of experiments for the purpose of testing the lenses of different makers, the negatives of which were produced, as he thought they would be more satisfactory evidence than the prints from them of the working of the lenses. These negatives being all taken on the same day, with the same chemicals, and with the camera in the same position, were considered to be a very fair comparison. His house, an old-fashioned residence, broken up by gables, offered an excellent object, not only from the large number of planes it presented, but also from the position of his vinery, the latter of which was about central between the house and the camera. The point of view selected was some seventy feet distant from the main buildings, and from this place the whole of the pictures were taken. Their chief object had been to see how far they could get the vinery and house into focus at the same time. The first was taken by Dallmeyer's triplet, eighteen-inch focus, exposure thirty seconds, without sun. This plate gave an excellent definition of the image up to the extreme edges, and was especially remarkable for the absence of all distortion in the perpendicular lines, so fruitful a source of annoyance in architectural subjects generally. The second, by a Petzval lens, focal length twelve inches, exposure twenty seconds, the sun being out bright, gave a definition of the *central* portion equal to the triplet, but with a tendency to *curvature* in the outer lines. The third, by Voigtländer's single lens, seventeen inches focal length, was exposed, in sunshine, sixty seconds, producing a sharp clear picture in the centre, but falling off materially towards the edges. The fourth was from a Grubb's four-inch aplanatic lens, twelve-inch focus, time of exposure, with sun, ten seconds, which gave a very much diminished image, but included, of course, a much *larger angle* than any of the preceding ones: the definition up to the edges of the plate was good, but a slight curvature was observable. The fifth, was by a Hermagi's portrait combination: this picture was an instantaneous one, with sun, and showed the powers of the lens to be very great, defining with equal clearness a figure against the vinery, thirty-five feet at least from the camera, and buildings at more than double that distance; the outer edges of the plate were not so clearly defined as could be wished, but the lens was evidently overtasked. The sixth, a portrait from Dallmeyer's triplet, with the central or negative combination removed, was exposed in the open air four seconds; but, being taken towards evening, shows a falling off in the actinic power of the light, and at the same time shows also that the triplet is scarcely available for portrait purposes, and *ought not* to be so applied except under extraordinary circumstances. The various negatives were separately and critically examined with much interest, and there seemed an unanimous opinion that Dallmeyer's triplet, from its rendering the lines of architectural subjects, especially, perfectly true and perpendicular and entirely free from distortion, was far superior to either of the others. Although the specimen produced did not show so large an amount of illumination as the others gave, still the detail was equally sharp, and as clearly defined at the edges as the centre.

Mr. Plante asked what form of lens Dr. Anthony thought best suited for enlarging purposes?

Dr. Anthony stated that for enlarging negatives he had never met with any single lens that gave him perfect satisfaction. In a negative of stereoscopic size there was often a great deal of beautiful detail, which rendered it very desirable for taking an enlarged picture; but neither Voigtländer's, Ross's, or Dallmeyer's lenses would bring out the detail with the distinctness that he desired, for directly the copy passed the size of the original, it began to fall off most fearfully about the edges. For copying such pictures it was better, instead of trying to do too much at once, to take a positive only a little larger than the original negative, and then again copying that, and so on for several times. By so doing they would get a negative that would print beautifully, and show no distortion. Instead of using a single lens in such cases he used a portrait combination, with the stop placed close down before the front lens: by that means the size of the picture was limited, but it was made particularly soft.

Mr. Turner said that would make it like the Lerebour lens, in which the stop was always before the front lens.

Dr. Anthony said that placing a stop in front of a portrait combination, though it had been the custom, was about the worst possible position; because, though a stop in front produced a better definition at the sides of the picture, and so was useful for taking groups, and copying from a plane surface, yet the field was found to be much diminished; the time of exposure to be nearly, if not quite double, that with a *central* stop; and, as Lake Price had correctly stated in his *Manual of Photographic Manipulation*, "the stop in front of the lens gives a *flatter* picture, but placed between gives a larger picture, with more depth of focus in the centre." A smaller stop does not always improve the definition, and beyond a certain point would rather tend to injure it.

Mr. Turner stated that he found the Lerebour arrangement to work very well in taking portraits, and especially if taking a group.

Dr. Anthony: As I before said, for groups the stops would be better in front, as it thereby corrects in some measure the curvature of the field, but at the expense of a diminution in size.

On the subject of Grubb's lenses, Dr. Anthony stated that he had found Grubb's landscape lens to take in a very much larger angle than any other—indeed, that quality might be seen in the very fine photograph on waxed-paper (Conway Castle) sent for exhibition by Mr. Robertson, of Manchester; but, at the same time, he must say that with a test he was in the habit of using, viz., some fine wire lattice in a dairy window, he could not get as satisfactory a definition with a Grubb as with his other lenses.

[The report of this and the Manchester Society, are condensed from the official organ of these societies.]

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 15th May, 1861.

M. Ferrier, whose stereoscopic views have for so long a period been the admiration of the world, has effected an improvement in taking instantaneous pictures which may be pronounced truly remarkable. At the last meeting of our Photographic Society this artist exhibited some stereoscopic pictures of singular excellence. One representing a boulevard of Paris, at a time when it is most crowded with fashion; horses, carriages, and pedestrians in continuous motion are represented as clearly and perfectly as if they were taken while at rest. This result M. Ferrier arrives at by adding a little *formic acid* to the developing solution of protosulphate of iron. The accelerating power of formic acid had been previously established in the use of the bath of nitrate of lead, in which a small quantity of this acid was accidently formed. Taupenot plates prepared in this bath required only one-third of the ordinary time of exposure, but the pictures had not the desired solidity which characterizes those of M. Ferrier now exhibited. I should not omit to state that these remarkable views were taken with Mr. Dallmeyer's new stereoscopic lens.

By acting upon sugar of milk with bromine, and decomposing the bromide so obtained with oxide of silver, Dr. Barth has discovered a new acid analogous to saccharic acid.

The recent researches of Bunsen upon coloured flames have suggested to M. G. Merz to study the colorations produced in flames by many substances, in order to arrive at a generalization in the employment of these colorations in qualitative analysis. The substances with which he experimented were nitric and and nitrous acids, phosphoric, sulphuric, boric, and chromic acids, potash, soda, lithium, barytes, strontium, chloride of copper; the results of his experiments were satisfactory and conclusive, and leave no doubt that analysis will be enriched with new resources by this method.

Signior Giovannetti has sent to our Photographic Society some positive proofs obtained in writing and printing inks, by a new process of which he has not yet supplied any details. The specimens have the aspect of proofs obtained by the salts of silver. If this process should prove practicable, it would not be rash to predict "another revolution in photography." We must await the discoverer's pleasure for the particulars.

M. Lavigne, who has made the subject of toning baths his special study, prefers to use such as consist of chloride of gold and hyposulphite of soda. The gold without the hyposulphite yields very rich tones; but M. Lavigne recommends particularly, when adopting this method, to employ the following formula:—

Chloride of gold and potassium	15 grains
Chloride of sodium	150 grains
Water	7 pints

Some experiments, undertaken by M. Van Mônckhoven, lead him to conclude that the sensibility of iodide of silver to light is greatly modified by the presence of other substances. His suggestions will open a new field for research from which important results to photography may be expected.

Doubtless many of your readers are engaged in the cultivation of the potatoe. Many remedies have been proposed for the disease with which this valuable plant has been afflicted since 1847; their use has been attended with more or less success. M. Martellière suggests the following, as a simple and efficacious means of preserving the potatoe plant from disease. Immediately the plants are in full blossom, say about the middle of August, a flock of sheep are turned into the field to pasture; at first, for a couple of hours a day, then for one hour, and afterwards for half an hour a day, until the end of the month: and again a few times during the month of September. The shepherd must keep the flock moving about the field, so as to operate equally. About an hundred sheep are sufficient for ten acres of potatoes. In gardens, the potatoes must be manured with sheep's dung. This method has been tried for five successive years, with invariable success. On those fields to which the sheep were not admitted, the potatoes were all attacked with the disease.

The Abbé Laborde has observed a new and important property of phosphorus, the knowledge of which may prevent many serious accidents in the manipulation of this combustible.

Take a stick of phosphorus, quite dry, and scrape it with the blade of a knife, so as to detach some fragments, and collect them on a sheet of paper. So long as they remain detached from each other they do not alter their appearance, but the instant they are brought into contact they suddenly melt, and undergo a semi-fusion; the temperature rises, and sometimes inflame spontaneously.

If instead of detaching the light fragments of phosphorus a thin slice is cut off, in a few moments the edges melt, and if the fusion is rapid, spontaneous inflammation becomes imminent.

THE TANNIN PROCESS.

Sir,—In the descriptions of the tannin process, hitherto published, I have not read of any other solvent than water being employed to moisten the film before development; I have developed six negatives (stereo) without any appearance of a wrinkle, or slipping of the film; by first wetting the film with diluted spirit, and rinsing it off with plain water (to prevent oily lines) it appears to me that the spirit effects a rapid solution of the tannin, and thus prevents the swelling effect, and consequent lifting of the film. I have used methylated spirit 1 part, water 5 parts. Hot water in place of cold, it seems to me may have a like effect.—I am sir, yours respectfully, Wm. Bartholomew.

Fareham, May 11th, 1861.

Photographic Notes and Queries.

Difficulties in Albumizing Paper.

Dear Sir,—I have been trying to albumenize paper, but do what I will I cannot get the albumen to dry equally on the surface—streaks of a dark brown shade showing themselves on the finished proof. Can you help me in this difficulty, or tell me how commercial albumenizers manage to overcome it.

I will briefly detail to you how I proceed. To the whites of 15 eggs I add 5 ounces of water and a few drops liquor ammonia, beat into a froth, skim off as it forms, and put into a flat dish to subside; after standing a week filter into another dish for use; float one minute, pin up by *two corners* to a piece of tape stretched tightly along a wall. I have also tried pinning up by one corner, and every other method I could devise, but always the same result—*inequality*.

Perhaps I should succeed better could I albumenize a whole sheet at a time, instead of pieces of the size on which this is written.—Yours, &c., R. E. M

[We cannot say with certainty the cause of the streaks to which you refer. Mr. C. Jabez Hughes, who has devoted much time and attention to the subject, attributes them solely to defects in the paper, which is unequally absorbent. Mr. Sutton states that a little acetic acid added to the albumen will cure the evil. We cannot say with certainty what plan is adopted by professional albumenizers; but we believe that many of them use acetic acid. Try it; and in any case omit the ammonia. Ed.]

Moule's Photogen.

Sir,—In your last week's journal you inserted a report of the Newcastle Society, containing the substance of a letter sent them by Mr. Moule, wherein he states that 300,000 portraits had been taken during the past season. This number would require between 40 and 50 tons of composition. From my knowledge of night portraits, and the number of those that are taking them, together with the want of confidence on the part of the public to have them, I am induced to believe your reporter has been mistaken in the figures, which would be most likely (if not corrected) to mislead many of the poor photos,—trusting to your usual courtesy for my excuse, I am sir, your your obedient servant, H. W.

London, May 15th, 1861.

[Our details were received direct from the society, and are, we believe, correct, so far as the society is concerned. If there be any error, we conceive that it may inadvertently have crept into Mr. Moule's letter. We will call his attention to the matter, when he will doubtless be happy to explain or confirm the statement.—Ed.]

TRANSFERRING COLLODION POSITIVES TO PAPER.

A new process, superior to leather, enamelled cloth, &c., for certainty, beauty of picture, and ease of manipulation, is the following:—

Take of india-rubber, such as is used for belting, one ounce, and dissolve it in two ounces of camphine. Take three ounces of asphaltum and dissolve, by gentle heat, in six ounces of turpentine and eight ounces of boiled oil; when it is all dissolved, add the dissolved rubber. After letting stand a few days to settle, decant into a flat dish and float your paper (common letter-paper is as good as any) upon it, hanging up by the corner to dry. Repeat the process until you have a smooth surface. If the solution is too thick, add turpentine and boiled oil in the ratio of six of the one to eight of the other. Keep the paper free from dust and it will keep any length of time.

After taking your picture and drying it, pour on alcohol, slightly acidified with nitric acid, say three drops of acid to one ounce of alcohol, letting it rest while you coat your paper in the same way: drain off into the bottle for future use. Then, with the plate in one hand and the paper in the other, dip in clear soft water several times, after which, lay the plate on the table, collodion side up, and put your paper upon it, rubbing it gently to free it from air-bubbles and superfluous fluids; when smooth, it is ready to be taken from the plate, be the time more or less; dry and mount. Thick collodion is better for transferring than thin.—*Humphrey's Journal.*

A new photo-lithographic process has been patented in France. It is invented by an English gentleman residing in Brussels, Mr. Wm. Toovey, brother of the water-colour artist. The photograph is produced at once on the stone without any intermediate operations. Full particulars are not yet announced.

Talk in the Studio.

Photography and Physiology.—An important scientific work is in course of issue in Munich—a Photographic Atlas of the Nervous System of the Human Frame. The photographs are taken by Herr Albert, the Court photographer, and are done with clearness and precision. There is an explanation published with the plates, in German and French, by a Professor of Anatomy; and the work is to be completed in ten parts, each part containing five plates, and costing about 11s. 6d. The first part is published, containing the nerves of the head, which stand out as plain and as fine as a spider's web in the photograph. The importance of such a work for students of anatomy can hardly be exaggerated; and, as I believe nothing of the kind is already in existence, it is a great honour to Munich to have led the way.—*Athenæum.*

Photography in the Witness Box.—Photography has frequently been called upon as an unerring witness in law cases, both civil and criminal. A case which recently came under our notice called into exercise an amount of decision and promptness in emergency that rather reminds one of a clever piece of military strategy than anything else. A case for compensation was under the attention of the Vice Chancellor's Court, in which a gentleman represented that his little rural paradise, a romantic and beautiful retreat from a noisy and irreverent world, had its sacred quiet invaded and destroyed by the immediate proximity of a railway. This retreat, which was, we understand, little better than a barn, was painted in glowing colours in the affidavit of the plaintiff. To show the real facts, defendants were anxious to have a photograph of the cottage to bring before the Court; but the plaintiff had stoutly resisted this, and kept watch that no photograph should be taken. At the last moment, the night before the case came on for hearing, application was made to one of our correspondents to take a view by strategy, and have a print in Court by ten o'clock the following morning. Nothing daunted by the difficulties and short time, he undertook the commission. The next morning was perhaps the most anti-photographic of the whole year: fog, snow, and rain. He arrived at the spot, some miles from his home, at seven in the morning, when it was barely light. During the night a couple of "navvies" placed at his disposal by the railway Company, had erected a rude platform to allow the camera to peep over a high wall, with which the house was surrounded. By his direction they tied back such boughs of trees as were in the way, and all was got into order whilst the unsuspecting plaintiff and his household slept. Everything was made to look as orderly as possible again, and a Fothergill plate being placed in the camera was exposed for one hour. It was then developed in a tent on the spot and found all right, and was dried and varnished. A sheet of paper was then sensitized in the tent, and placed with the negative in the printing frame, which was tied upon the top of the cab to print, and the driver told to drive to court like mad some half-dozen miles off. On reaching court the print was sufficiently done, and was mounted by means of four wafers on a piece of card-board, and curtained with a piece of yellow paper, being unfixed. It was ready we believe just two minutes before the time. Its effect in the court we did not hear, but it ought to have been successful, simply as a reward to promptness and skill.

Photography and the Art Critics.—It affords us intense satisfaction at all times to watch and record the gradual, but sure progress which photography is making in establishing its ground for consideration amongst the Art Critics. The *Athenæum* in a notice of the Exhibition of the Royal Academy just opened, speaking of a painting of the "The Ruins of the Temple of the Sun at Baalbec," by David Roberts, the acknowledged prince of architectural painting, compares photography favourably as contrasted with the picture, and remarks: "It is not to be denied that there is a certain mechanical grandeur in this picture; but as to its affording anything like a literal and faithful representation of the subject whose name it bears, the idea is preposterous. The columns and temples *may* occupy such and such positions, singly and relatively; but, out of so mechanical and artless a representation, it is hopeless to get any idea of those feelings of desolation, voidance and ruin which the place itself never fails to call up. We have seen photographs which were awfully grand in comparison—indeed, were really so, because they gave us the city that has stood amidst sands for a thousand years or more."

To Correspondents.

J. A. Glo.—The yellow spots in your print appear to arise from imperfect fixation. The hypo has been too weak or too old, or too many prints have been immersed at once. The spots appear to consist of the insoluble hyposulphite of silver. In other respects the print is a very good specimen of the process. A little longer exposure would have brought out all the detail in the foliage, and made the negative all that could be desired.

A Female Artist.—The cost of protection by registration varies somewhat according to the article to be registered. Provisional registration costs, we believe, from about £3 to £5. A patent agent will supply you with full information. Write to B. Browne and Co., patent agents, 52, King William Street, E.C. The reduction for a quarter's advertisements will be ten per cent.

C. Barker.—The lines in your negative arise from the action of light upon the nitrate of silver running in greasy lines down the plate. The light is refracted by the streams of solution. See Mr. Thomas's article on streaks, in the present number, and our own remarks on the subject. We do not think yours a common form of streaking, but Mr. Thomas's suggestion meets the case.

Colby.—The best "optical glass" for lenses, is made by Chance, of Birmingham. Mr. Hughes's work is just out, and the price is one shilling.

J. F.—You will find a method of transferring collodion positives in the present number, and various processes have been given from time to time in our columns. One of the simplest methods is as follows:—Dry the picture, and then pour on and off two or three times a little alcohol and nitric acid, about ten drops of the latter to an ounce of the former. Then treat a piece of black glazed leather in a similar manner, whilst the surfaces are wet; press them closely together, taking care to exclude air bubbles. Now place them in a pressure-frame for about half an hour. At the end of that time the leather may be lifted from the glass, and will bring with it the film. A tough collodion of good body should be used.

N. W.—If you adopt Mr. Barber's plan of purifying the silver bath by means of oxide of silver, the bath after filtration will generally be found slightly alkaline, from a minute portion of oxide of silver in solution. The addition of acetic acid will now by combination with the oxide, form acetate of silver, and thus produce the conditions laid down as necessary for Ponting's collodion. You may frequently use the recrystallized silver sold as pure, but you cannot be absolutely certain. Results are the only reliable guide.

M. N. B.—Print a little deeper and remove the prints from the toning bath before they have acquired the cold blue tone. Your negative is scarcely sufficiently vigorous to give the best results. The stain is the result of handling the excited paper with fingers which had been in hypo. You must be cleanly and careful if you would succeed in photography.

W. L.—We are much pleased with your specimens. The performance of your lens is very satisfactory. We will insert your name.

L. A. D.—Your picture is not quite sharp, but it is in other respects very good. We have not had experience in using the hot press; but may state that the face of the picture should be next the hot plate, and nothing soft need be placed between it and the roller.

C. C., Belgium.—It is difficult to advise you as to price, as it is a point of which you are the best judge. We should say about 2s. 6d. or 3s 6d. It will be better to send them mounted, but not glazed under the circumstances.

Michael L.—The specimens are very respectable and decidedly indicate progress. But they are sulphur toned. Why don't you try the alkaline gold bath?

Clayton.—The picture should not be fixed, but developed with iron, well washed, the iodine solution applied, again washed, and then intensified with pyro and silver. If you simply apply the iodine solution without further intensifying with pyro and silver, you convert the deposit already there into iodide of silver, which is very readily soluble in cyanide of potassium. If the image is dissolved off after you have intensified, it is because you have not intensified enough, and you use the cyanide too strong.

L.—We are obliged by your communication, and will give it early attention.

G. W. Hale.—Only your letter has arrived as yet. We will give you our opinion with pleasure when the pictures arrive.

Charles Hathsone.—Considerable confusion exists in the terminology used to describe the various qualities and strengths of acetic acid. The acetic acid of the P.L. is a little more than half the strength of the glacial acetic acid solid at 60° Fah. Beaufoy's acetic acid is a very indefinite term indeed, as Beaufoy's send out three or four different qualities of acetic acid. Their best is a little stronger than that of the P.L. We shall enter more minutely into the subject shortly, in our series of articles on "Photographic Chemicals."

W. Deane.—Bromides are added in small proportions, of generally from one fourth of a grain to a grain, in conjunction with the usual amount of the iodide, to give additional sensitiveness to the collodion when developed with iron, and to produce softness and cleanness in the picture.

W. H. N.—We have not used the collodion you name, but suspect that it is scarcely intense enough for your purpose. Expose a little longer, and continue the use of the pyro and silver longer. If you do not gain sufficient intensity wash well, and then apply a solution of bichloride of mercury; you can by this means gain any amount of intensity. The toning is scarcely deep enough; but without a more intense negative you cannot get deep tones.

D. Hills.—We do not know of any good whole plate lens for sale second hand at present, such are, however, constantly announced for sale in our advertising columns.

Herbert Ogg.—A correspondent asks us if we can give him any information of the address of this gentlemen who is a photographic colourist. If Mr. Ogg will write to us, we will forward the address.

Phos., G. S. Penny, and W. B. Fawcett, are thanked for communications which shall receive early attention.

S. F.—Considerable improvement, but still not sufficient exposure. We fear the collodion is faulty. Try some fresh. The print is a little too deeply toned.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 142.—*May* 24, 1861.

SHARPNESS *versus* HARDNESS.

One of the earliest discussions which agitated the Photographic Society immediately after its establishment, and found the devotees of art, and the representatives of science, arrayed against each other, arose out of a consideration of the true character and use of sharpness. A discussion similar in character, but in a milder form, arose out of Mr. Wall's paper the other evening at the South London meeting. We cannot help thinking that the objection to sharpness on both occasions has arisen from some misapprehension of its true character. Disgusted with hard pictures which were vaunted as sharp, Sir William Newton proposed, for producing certain artistic studies, to turn the lens a little out of focus. In the absence of the softness produced by true gradation, he would prefer the bastard softness produced by blurring the lines of the picture. To the painter, this idea might naturally arise, as suggested by the manipulations of his own art, in which the sharp hard lines of the pencil are "softened" by blending them with the badger-hair "softener." The nature of the tools and of the results in the two Arts are, however, essentially different. The perfect gradation of a well lighted object, as given by a good lens on the ground glass, is immeasurably softer and more beautiful than the finest picture which can be produced by the pencil; and if that image be faithfully reproduced in the picture, it needs no touch of the badger tool to satisfy the most artistic eye. If it did it is very apparent putting the lens out of focus would not really soften the picture, but spoil it. As M. Claudet at the time remarked, "If we push the tube out, the parts before the face will be more confused than they were before; and if on the other hand we push it in, the parts behind will be more confused than they were before. The difference will be incongruous in both cases, either for the nearer or for the more distant parts. The confusion in these parts will be such that the drawing will be false, and the outline deficient."

In the discussion the other evening, Mr. Wall did not propose to get rid of sharpness. He admitted that he had disliked the word, that he had decried it, and had both publicly and privately called it hard names; but when he had now carefully set himself to the enquiry "what is it?" he began to suspect that it was after all an old friend of his, and which in his pictures he would not willingly lose. The true culprit was hardness, but he had so often heard hard pictures praised for sharpness, that he had come to regard the two terms as almost synonymous; and he could not readily bring himself to believe that a large majority of photographers did not entertain similar error, and quoted various photographic authorities in favour of his opinion. Lake Price, for instance, condemns the "parrotry of sharpness." But it should be observed here that Lake Price does not condemn sharpness, but the "parrotry" regarding it: that is the unintelligent and unappreciative use of the term; and the perpetual lauding of it as a substitute for all other artistic qualities.

That it is possible to sacrifice almost every other artistic quality to something which shall be called sharpness, there can be no doubt. We can recall to our mind at this moment portraits taken with the full aperture of a lens of short focus placed nearly close to the sitter. The huge Cyclopean eye of the lens looks not only at, but over, and under, and all round, every inequality in the texture of the skin. And instead of giving an image such as the human eye would see, it yields a monstrosity, in which the velvetty skin is as rugose as the hide of a rhinoceros. And yet the first impression conveyed to many minds is one of amazing sharpness, and the pictures get praised for that quality. We have again seen pictures of essentially opposite character. We have seen landscapes and bird's-eye views of towns in which by the use of the smallest possible of stops, sharpness was distributed over miles of space: flat, hard, adhesive pictures, in which the parts had no separation or relief, the extreme distance being glued fast to the foreground; atmosphere was ignored, and the picture of miles of space presented no relief whatever, the effect being similar to that produced by looking at the scene with one eye, and that through an aperture little larger than a pin head. Such pictures also have been praised for sharpness. We have also seen pictures without any of these enormities, perfect enough in proportion, but possessing only a few keen microscopically sharp lines of black and white, without the slightest gradation of tone or detail, and these also have been praised for sharpness; we presume, in deference to their sharp contrasts, if to nothing else. We can understand therefore, that Mr. Wall, looking at the matter purely from the stand-point of the artist, should have been ready to decry this quality, which amongst certain photographic critics has often been made to do duty for so much else. We have heard an ill-natured remark, to the effect that when a young lady is described as being amiable, it is a sure sign that she is neither clever nor beautiful. Following the same idea, it has been too common a criterion of the absence of artistic qualities when a picture has been praised for sharpness.

It would be as absurd, however, to regard sharpness as a bad quality in a picture, as to regard amiability as a disagreeable characteristic in a lady, simply because they each, amongst a certain class of critics, have been made to do duty for other qualities; and we cordially endorse the remarks of Mr. Hughes in which he regards sharpness, that is, perfect definition, as one of the primary and most vital essentials of a good photograph. Indeed, in a certain sense, we are disposed to regard perfect sharpness as absolutely essential to, if not entirely identical with, perfect softness. Perfect delicacy of gradation is necessary to softness; and entire sharpness is, to our apprehension, necessary to delicacy of gradation. The sharper or more perfect the definition, the finer the lines or points; and the finer the lines or points the greater the number of them in a given space; and the greater the number of lines or points of varying luminosity, the more perfect the gradation, and, of course, the softness. Take a carpet, or any other textile fabric, as an illustration. The finer the threads the more soft and perfect the gradation in the pattern. Every school girl knows that the finer her canvas and thread, the more delicate become the patterns of her embroidery. Sharpness is, therefore, as Mr. Howard stated, an absolute necessity of anything like perfection in small pictures.

We are not about to discuss here whether we should adopt the principle of securing microscopic delineation on a mathematical plane and over a limited field, or whether an inappreciable amount of astigmatism may not be tolerated in order to secure other advantages. We are merely asserting that sharpness is not antagonistic to artistic qualities, but rather essential to their full development. The works of all our best photographers might be adduced in illustration; but we will content ourselves by referring to two. In portraiture we believe it is universally acknowledged that the vignette heads of Mr. T. R. Williams, are unequalled or unsurpassed by the productions of any other photographer. Yet it will be at once admitted, on examination, that they are amongst the sharpest, as well as the softest specimens of our art. In landscapes, we know of nothing surpassing the pictures of Mr. Mudd: take Coniston Falls, a picture now familiar to many photographers. In it we have gradation after gradation of distance, all perfectly defined; but without the slightest degree ignoring relief or atmosphere. After the effect of linear perspective the all-important element in giving true effect to distance, in a landscape, is atmosphere, by the influence of which light and shade and colour all lose their contrasts, and details cease to be made out: forms are not, however, altered; they are still defined, however faintly: there is neither distortion nor the blurring of imperfect focus; and when the latter qualities are present in the photograph they are blemishes not beauties. The artistic photographer will always preserve his chief focus, both definition and of light—using "focus" in an artistic sense—for the principal object in his picture, but he will aim at getting due definition everywhere. He will aim at obtaining sharpness; but in the right place, and distributed in its proper relations throughout the picture.

INSTANTANEOUS PHOTOGRAPHY.

Dallmeyer's Stereoscopic Lenses.

Amongst the most notable photographs figuring in the present French Exhibition are some remarkable instantaneous pictures by Messrs Ferrier (father and sons) and Soulier. They are described by *Le Moniteur de la Photographie*, as the most perfect things of the kind ever produced; and from their subjects necessarily involve the conditions of complete instantaneity to obtain any degree of success.

They consist chiefly of views of one of the most crowded Parisian thoroughfares, the Boulevard de Sebastopol. Not one of a thousand figures of all kinds, foot passengers and vehicles passing in all directions, shows the slightest sign of movement or imperfect definition. Figures standing in the shadows of porticoes are all perfectly rendered, although the exposure was but the imperceptible fraction of a second. To produce these pictures the lenses have been procured from England—Mr. Dallmeyer's stereoscopic lenses having been selected. *Le Moniteur* reporting upon them says:—

"Messrs. Ferrier and Soulier have made numerous experiments with these instruments, and have communicated to us the results.

"These artistes have proved that these lenses give a more luminous image than any instrument made up to the present time, that without any diaphragm they give a large field rigorously clear and well defined, that the image is quite free from aberration of perspection and nearly so from aberration of sphericity. This last, when at all apparent, is in the opposite direction to that seen in lenses generally; but in the present instance the defect is so slight, that it may be considered as *nil*. With a diaphragm the image is quite perfect.

"The short focus enables the operator to work with the greatest rapidity, and also permits him to photograph objects from which it would often be impossible to retire sufficiently far distant with a lens of long focus.

"The apparatus is so arranged that the front lens of the combination may be used as an ordinary single view lens, which gives excellent results for landscape work, with a stop of one centimetre, or a little more than three-eighths of an inch.

"It is with the stereoscopic objective of Mr. Dallmeyer that Messrs. Ferrier and Soulier have executed the greater part of the remarkable instantaneous pictures described in another column."

We feel gratified that a firm, so celebrated for the excellence of their stereoscopic results as Messrs. Ferrier and Soulier, should send from Paris for the instruments of an English optician, and should so ungrudgingly accord their high meed of praise to them; and we feel additional gratification that our opinion, more than once expressed, of the value of these lenses, should receive such satisfactory endorsement.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Clair-obscure.—A French term, the meaning of which is the same as chiaroscuro, for which it is frequently used.

Classic.—The great works of ancient art are termed classical, but the term is also applied to the best productions of really great modern masters. The word is said to have been derived from the term *classicus*, which originally meant the higher order of citizens.

Clearness.—A quality more frequently applied to the harmony of colouring; but of importance as affecting the harmony of tones, and the proper effect of atmosphere. Clearness is a quality of the picturesque which is so much a matter of feeling with artists, that when asked to define it they are generally somewhat at a loss, and can more readily tell you what destroys it, than what constitutes its being. The most essential elements of clearness are gradation, force, and breadth of chiaroscuro. The most powerful of its destroyers are a want of gradation and the absence of atmospherical effect. The photographer's white sky, by rendering every gradation of tone in the picture false both to nature and art, strikes clearness dead at once; and so does large, unbroken masses of light or dark when of an even monotonous tone. J. B. Pyne, in a series of practical articles which were very highly appreciated by artists, and which appeared in the *Art Journal*, under the title of "The Nomenclature of Pictorial Art," says, "The quality of clearness at its maximum results from the coincidence of a full harmony of colour, in very moderate force—*aerial perspective*—a frequent alternation of the transparent, semi-transparent, and opaque media,* *distinct detail, and bold chiaroscuro.*

Close.—A view shut in by trees, or which gives but little distance, is termed a close view. Such have been more frequently successfully rendered by photography than views representing greater varieties of distance.

Composition.—The composition of a picture indicates the conception of the artist, and, as a whole, must be regarded as the exponent of his sentiments and feelings. By it we are instructed to consider the character of every portion in reference to unity,† harmony, and keeping; so that no part of the picture can refuse to co-operate with every other part, in conveying to the spectator's mind the feelings by which the artist was influenced in his selection and treatment of the subject represented. Composition may be held to take in every branch of study connected with the picture's progress, and all the rules and principles I have, or shall endeavour to enforce are, strictly speaking, part and parcel thereof; but in its higher sense it is more closely connected with the painter's loftier aspirations to which all these are but as means to an end.

In one of my earlier papers, "From a Photographer's Common-Place Book," I took occasion to point out the difference between the artistic and the photographic meaning of this word; and my very excellent and able friend, Mr. Hughes, in a paper read before the South London Society, also pointed out the mischievous tendency which the misapplication of such a term had when applied to artistic photography. Composition implies that every part of a picture is associated with the whole. This must not be overlooked when the objects you are photographing are examined upon the focussing glass. They should be

* These papers were, of course, addressed to the painter only. The italics indicate those qualities which have a photographic bearing.

† "Composition implies the putting together of parts so as to constitute a whole; but the parts or divisions must be distinct, or there will be no apparent composition."—H. Howard, R.A.

chosen, rejected, or altered in appearance, by a change of position, solely in reference to the feeling, sentiment, or thought you desire to express.

Of course if your only aim be imitation without selection, or selection with a view to mere common place photography, composition, like nearly every other artistic principle of rule, will be of small use to you. But if you select a view which speaks to your own mind of poetical sentiments, lofty ideas, or particular beauties, associated with certain trains of thought, and desire to embody these in your finished picture, you will then begin to analyse the scene and discover the peculiar features thereof to which such effects may be more clearly attributed. Then you will turn to the focussing glass with studious and anxious earnestness:—will not throw off the dark cloth and pull out the ground glass directly you see the image is sharp; but will carefully consider it in regard to composition. Taking both the intended size and shape of your picture into consideration, with a view to *excluding* anything that might exhibit characteristics at variance with your aim or design; and *including* everything of value to the same.

A picture so produced has given, as it were, new life and speech to a portion of the artist's soul; for his living thoughts are so embodied therein, that they commune with all who see them.

Ruskin says,* "The landscape painter must always have two great and distinct ends; the first, to induce in the spectator's mind the faithful conception of any natural object whatever; the second, to guide the spectator's mind to those objects most worthy of its contemplation, and to inform him of the thoughts and feelings with which these were regarded by the artist himself.

"In attaining the first end, the painter only places the spectator where he stands himself; he sets before him the landscape and leaves him. The spectator is alone, he may follow out his own thoughts as he would in the natural solitude, or he may remain untouched, unreflecting, and regardless, as his disposition may incline him. But he has nothing of thought given to him, no new ideas, no unknown feelings, forced on his attention or his heart. * * * But in attaining the second end, the artist not only *places* the spectator, but *talks* to him; makes him a sharer in his own strong feelings and quick thoughts; hurries him away in his own enthusiasm; guides him to all that is beautiful, snatches him from all that is base, and leaves him more than delighted, ennobled, and instructed."

Now that these eloquent remarks are applicable to camera-art, although not so comprehensively as to the painter's, will, I think, be acknowledged by photographers who have thoughtfully followed me through these papers. The truthful rendering of nature is a question which mainly concerns the photographer's manipulation, management of lens, and chemical knowledge; subject, of course, to a rightful conception of what really constitutes truthfulness. But for "guiding the spectator's mind to those objects most worthy of its consideration," we can but look to the intellectual powers of the operator as an artist.

It does not affect the question to point out the different nature of the artist's appliances and the photographer's; because although the latter must translate composition by pure selection we see too many paintings which, while admitted to be photographically true to individual nature, begat some of the brightest thoughts which have emanated from the loftiest minds among our art critics.

In the work quoted above Ruskin, says:—"The simple statement of the truths of nature must in itself be pleasing to every order of mind, because every truth of nature is more or less beautiful; and if there be a just and right selection of the more important of these truths, the facts so selected must, in some degree, be delightful to all, and their values appreciable by all; more or less, indeed, as their senses and instinct have been rendered more or less acute, and accurate by use and study; but in some degree by all, and in the same way by all."

And again, he says, speaking of selection:—"Nature's finest touches must be watched for; her most perfect passages of beauty are most evanescent. She is constantly doing something beautiful for us, but it is something she has not done before and will not do again; some exhibition of her general powers in particular circumstances which, if we do not catch at the instant it is passing, will not be repeated for us."

The above conveys a valuable hint.

The great element of all good composition lies in the power you have of imbuing with your own thoughts and feelings the otherwise inanimate and meanly useful photograph. No matter how the true artist communicates with us, whether by voice, pen, or pencil, he always knows that it is only that which he himself feels, which enables him to reach the feelings of others.

All I have written has been to show the command you, as a photographer, have over "composition," as understood by the painter. In pointing out the various means of securing effects, and their power and importance when secured, I have had, and shall continue to have, one object, viz., "composition." And now I will quit this definition, by pointing out how all the means here described are but tools to compose with, and that the aim and end of composition may be defined as the eloquent and powerful expression and preservation of all that is intellectual, noble, and beautiful in your own nature.

* In "Modern Painters."

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Chloride of Gold—continued.—The analysis of this expensive chemical is a point of great importance to all who are in the habit of purchasing much of it. It seems to be a law that the more expensive an article is the more shamefully it should be adulterated; and certainly chloride of gold appears to be no exception to this rule. A short time ago (see No. 123) we published some remarks by Mr. Reynolds on the amount to which this article was adulterated, in which he showed that in some cases the purchaser was defrauded to the extent of £23 8s. on every £100 worth sold, and adulterations to less degrees were very common. Fortunately there is scarcely any substance, the analysis of which presents so few points of difficulty to the unpractised manipulator, as the ascertaining the true amount of chloride of gold present in any sample, and we shall therefore proceed to give the full details of the best plan to follow in order to detect both the presence of adulteration in this chemical, and also the approximate amount of sophistication.

Chloride of gold is usually supplied in small stoppered bottles or sealed glass tubes containing (or said to contain) 15 grains of chloride. Take one of these bottles, and having removed any loose pieces of paper from the outside, weigh it carefully in a pair of scales, which should be at least sufficiently delicate to turn with a quarter of a grain. We will suppose the weight to be 32¼ grains. Now open and remove the contents to a small porcelain crucible, the weight of which is known accurately, washing out the last portions of chloride with a drop of water; dry the bottle and stopper perfectly, and weigh again. Subtract the less weight from the greater, and the difference will be the weight of the contents of the bottle. The following were the numbers obtained in an experiment of this kind:—

Weight of bottle and contents	...	32¼ grains
Weight of empty bottle	... ...	19½ „
Weight of contents	... ...	12¾ „

This showed that the dealer had defrauded the customer of 2¼ grains by short weight.

The crucible, with the contents and washings of the bottle are now to be heated carefully over a water-bath until all the moisture is driven off from the chloride. The crucible containing the dry residue is then to be removed from the water-bath and very slowly heated over a spirit-lamp, supported on a triangle of wire until chlorine has ceased to be evolved, and the contents are at a full red heat, and in a quiet state. Allow the crucible now to cool, and weigh it again when cold. The difference between the latter weight and that of the empty crucible will represent the amount of metallic gold in the chloride, supposing that it is not adulterated. Every 65·2 parts of metallic gold that is left in this way representing 100 parts of terchloride of gold, it is easy to calculate the quantity of the latter which the bottle originally contained. In the experiment above illustrated the following figures were obtained:—

Weight of empty crucible	$34\frac{1}{2}$ grains
Weight of crucible with gold ...	40 „
Weight of gold	$5\frac{1}{2}$ „

There were thus $5\frac{1}{2}$ grains of metallic gold left upon igniting $12\frac{3}{4}$ grains of the terchloride, and as according to the following rule

65·2 gold : 100 terchloride of gold :: $5\frac{1}{2}$: 8·4

it is seen that $5\frac{1}{2}$ grains of metallic gold only corresponds to 8·4 grains of terchloride, it follows that the dealer defrauded us out of 6·6 grains of terchloride of gold, instead of only $2\frac{1}{4}$ grains, as shown by the first weighing, a pretty good quantity to be fraudulently appropriated out of a fifteen-grain bottle; the difference being made up of moisture and acid.

For some years we have been urging upon photographers and dealers not to employ so deliquescent a salt as the chloride of gold, but to use in preference the *double chloride of gold and sodium.* This beautiful salt is easily prepared. Dissolve four parts of gold in nitro-hydrochloric acid, and evaporate as described in a previous chapter, dissolve the residue in eight parts of water, and add one part of pure chloride of sodium. Place the solution in an evaporating dish and evaporate half the water off, now place in a cool place and cover from dust, for it to crystallize. The double chloride will separate, on cooling, in the form of long orange yellow four-sided prisms; strain them from the mother liquor, dry, and preserve for use in a stoppered bottle. The crystals are quite permanent in the air, neither deliquescing nor efflorescing. 100 parts well crystallized in the above manner contain 49·5 parts of gold, 14·66 parts of chloride of sodium, 26·56 parts of chlorine in conjunction with the gold, and 9 parts of water.

The double chloride of gold and sodium can be readily analysed in the following way:—weigh out accurately 10 grains of the dry crystals, place these in a porcelain crucible and gently heat, gradually raising the temperature to full redness; water will be driven off at first, and then chlorine. The crucible must be kept at a full red heat for about half-an-hour, so as to make sure that all the chlorine is driven off, as this salt is not so easily decomposed as the simple chloride. When sufficiently heated, allow the crucible to cool, and then pour distilled water in. Boil the water by means of a spirit lamp, and then carefully pour it away from the metallic powder which will remain at the bottom. Fill up again with water, boil, and repeat the operation until the decanted liquid contains no chlorine when tested with nitrate of silver. In this way all the chloride of sodium is removed and the residue will be metallic gold. Now dry off the last traces of water, heat the crucible to redness for a minute, allow it to cool, and weigh. If the chloride of gold and sodium be pure, 10 grains of the crystals should leave 4·9 grains of metallic residue.

Chloride of Platinum is not of much use to the photographer, nevertheless, as this salt, as well as the corresponding palladium salt, has sometimes been used for toning positives, our account of the photographic chlorides would be incomplete were no mention to be made of them. Chloride of platinum is prepared by gently warming scraps of platinum foil or wire in a mixture of two parts nitric and three parts hydrochloric acid, care being taken not to let the liquid boil. The metal is gradually dissolved, and the solution must then be evaporated on a water bath with excess of hydrochloric acid, until it is dry. In this state chloride of platinum forms a dark brown mass, readily soluble in water. Its aqueous solution reddens litmus, has a very astringent taste, and stains the skin a brownish black. It may be analysed exactly in the same manner as the chloride of gold, and as every 100 parts of the anhydrous chloride contain 58·3 parts of platinum, the amount of impurity present can be at once calculated.

Chloride of Palladium is prepared by dissolving metallic palladium in nitro-hydrochloric acid, and evaporating in the same way as recommended for the platinum salt, but not driving off the whole of the acid. It forms a black brown fusible mass readily soluble in water, forming a deep yellowish red solution. If, however, the excess of acid be completely driven off by heat, there remains a brownish yellow crystalline mass which is only slightly soluble in water. Unlike the platinum salt, which is a terchloride, this is a protochloride, and contains in 100 parts 69·09 parts of metallic palladium. It may be analysed in the same way as the gold salt, but it requires to be kept for a considerable time at a red heat in order to drive off the last traces of the chlorine

SHARPNESS—WHAT IS IT?

If frequent use could wear out a word, where would that poor little word "sharpness" be? No quality has been more lauded, few more frequently denounced than that which has been held by photographers to be represented in this word. Sharpness has influenced the labours of our opticians, chemists, and manipulators; to its attainment far higher and more important qualities have been ruthlessly sacrificed; and it must certainly have seemed to many that if there was one thing above all others for which photography was providentially created, that one thing was sharpness.

I must admit that I don't like the word: it has become associated in my mind with hardness, and flatness, with a dull monotonous surface cut up into paltry little sections by sharp outlines, and the unpleasant and unnatural obtrusiveness of minute details. I have more than once expressed my feelings about it in the journals; have smiled with a sensation of gratified malice when it has been severely handled; have given it a vigorous dig in private conversation when I got the chance, and altogether have been anything but its friend and supporter. Having done all which I begin at length to suspect that the poor thing which has received so much ill-usage at my hands is after all a very worthy, good, and excellent friend of mine, deserving far different treatment. Not, however, being *quite* sure that my suspicions as to the character of this quality are justified, and not being the happy possessor of great scientific attainments myself, I come down to our pleasant meeting this evening with a few words about sharpness, written with the sole intention of enquiring from the scientific and experienced of our little fraternity—*what is it?*

In bringing forward this subject, however, I feel, to use the words of a friend of mine, that it is a difficult one to deal with, "because no one has ever fairly committed himself as to what sharpness really is, so that when you attempt to seize the fellow in one shape, *presto*, he assumes another denies that he ever was anything else than that he is, and protests that everybody's common sense knew him to be that." I shall presently show you that for want of a clear definition of this little work, much misunderstanding has divided artists and photographers; and to prove that the definition I ask for is not altogether so needless as some amongst us may think, I shall refer to such authorities as *Sir William Newton, Messrs. Buss and Leighton, Mr. H.*

Cooke, Mr. Rothwell, Lake Price, Professor Hunt, and Mr. Sutton; assuring you that to these I might easily have added a dozen or two more of good authorities, if I had possessed the necessary leisure to hunt out references.

I have been associated with photographers for nine or ten years, although my own *practical* experience in this delightful art dates from a more recent period. I have mingled with photographers, and discussed photography in many parts of England, and with operators of different degrees of merit, and of varied attainments in both photography, science and art; and it is from convictions thus strengthened that I feel this question of sharpness ought to be definitely settled.

The optician will, I suppose, define sharpness as "the perfect representation of a point by a point." The photographer, I know, frequently defines hardness as sharpness. And the artist is too apt to take the term for what it is worth in the dictionary, without due reference to its technical meaning.

I suppose sharpness really means the perfect definition of an object in focus. If this is true, what constitutes *perfect* definition? By what standard are we to judge its perfection? By the definition given in the image upon the healthy eye's retina, or that produced by an optical arrangement of glasses which gives the most clearly and distinctly visible view of every minute detail in the natural object? One lens will produce a sharper picture than another, and again by decreasing the aperture we can increase the sharpness; but what is the standard we are to set up for our guide in this matter? for unless we seek sharpness merely for the sake of sharpness, some standard of perfection we must or ought most certainly to possess.

It will show pretty clearly in what spirit this matter has been discussed by photographers and artists if I refer back to the first volume of the *Journal of the Photographic Society*. We there find that at the first ordinary meeting of that body, Sir William J. Newton, being both an artist and a photographer, read a paper "Upon Photography in an Artistic View, and in its relation to the Arts." In this paper its author, while regretting that photography had not then realized the truths of atmospherical perspective, pointed out, as a course for the photographer to pursue, the devising and discovering of means by which pictures might be produced "*still more minute and perfect in detail,*" without however forgetting "that his subjects are principally natural objects, powerfully acted upon by atmospheric influence." Sir William Newton wanted, in short, more "*gradation,*" and less "*flatness.*" and I think every *artist* photographer of the present day must acknowledge that this—speaking generally—is a want still to be supplied. In the course of his paper, however, Sir William observed that for the purpose of the painter only, and "*as private studies,*" a "greater breadth of effect" would be attained if the photograph were taken "*a little out of focus.*"

Now the great aim of the painter has always been to secure for his compositions that harmonious unity of parts which constitutes a perfect whole; and not only are crude spots or patches of light, dark, or colour destructive of this, but sharp edges and abrupt terminations have an equal tendency to cut up the surface into sections, and so destroy breadth, or in other words, the unity of parts: separating and dividing instead of uniting, giving you a weak little bit at a time, as it were, instead of coming down upon you at once with the whole strength of well united forces. For this reason Sir William advised the artist, or the painter, to take his photographs, as studies, "*a little out of focus.*"

Now the excellent vice-president's doing this was nothing very terrible, but it seems to have startled the whole photographic world from its propriety. In vain Sir William asserted "he had no intention of advocating the *general* use of this plan," nobody seemed to believe him; and soon after, when the subject was re-opened by two papers read respectively by Mr. J. Leighton and Mr. R. W. Buss (artists both I believe) a grand battle-royal came off in the presence of Sir Charles Eastlake, President of the Royal Academy, at the end of which matters remained much the same as they were before they commenced, so far as the actual merits of the question were concerned. Mr. Buss asserted that by throwing objects out of focus forms were rendered indistinct, the minute detail or lines destroyed, and nothing left but large masses of light, half tint and shade; and Mr. Leighton that by excess of detail you sacrificed breadth, or in other words exactly the same thing. In the discussion that ensued Sir William remarked that the artist who copied servilely "destroyed the poetry of fine art," and argued that photography by copying *servilely* could never reach "the poetry of *Nature.*" Mr. Vignoles said, the artist, the optician, and the engineer each viewed these matters in a different light: but although he himself certainly desired more artistic qualities in photographs, he "should as soon think of attempting the adjustment of his eye instead of using a veil, as of throwing the camera out of focus to obtain an effect he could produce by a variety of other means." Mr. Shadbolt referred to the strong party feeling existing on the subject, and stated that he and Sir William Newton differed in toto "as widely as light from darkness." Dr. Percy believed accuracy and minuteness of detail to be perfectly consistent with breadth of effect, and therefore denied the necessity for throwing a picture out of focus. Mr. Henry Cooke, a painter, said, "the whole question of whether photography should be a benefit or a bane as an art, hung upon the successful issue of the pending question. He thought focus a scientific rather than an artistic question, but said if one part of a picture must be sharper than another, that part should certainly contain the principal object or objects. Such was the character of this often mentioned and very animated discussion, in which beyond agreeing to disagree, little was done by those present for settling the point at issue.

In reference to the assertion of Mr. Buss. I would remark that the destruction of detail is neither more nor less than the destruction of gradation, upon which real softness and breadth to so large an extent are dependent. I cannot remove detail from any portion of a photographed surface without removing certain of the more delicate tones which unite and blend the half-tints with the highest lights. For instance, suppose I take a brush, and with indian ink lay in a broad line, the edges of which are washed softly away into the white paper on either side; if I then take two pieces of straight edged white paper, lay them one on either side of the line, and gradually bring them closer and closer, until a very fine dark line alone divides them; this line, owing to the removal of the more tender and delicate tones on either side, must then appear sharp and hard. Therefore I think Mr. Buss was mistaken in supposing "the minute detail or lines" might be destroyed with advantage, and with reference to Mr. Leighton's remark, I could easily quote expressions from a score of eminent artists of the highest rank tending to show that in their opinion the most minute perfection of detail was perfectly consistent with a broad artistic effect.

Sir William Newton's objections to the servile copying of the artist I can understand. There are matters of higher importance which should claim all an artist's efforts and time, for such therefore to sit down and copy nature servilely is waste of their precious gifts by indulging in mere mental indolence and self degradation: but surely the more nearly we approach, by a process demanding no such laborious outlay of time and work, the truths of nature, the greater chance we have to embody her spiritual meaning or poetry. Sir William himself inferred the close ties which unite the poetry of art to that of nature.

I have in my own mind some suspicions that the quality which is somewhat commonly regarded by our practical operators as sharpness, is neither more nor less than imperfect focus, or in other words, not sharpness at all. I believe that perfect sharpness or focus tends to destroy outlines, secure gradation, and give perfect modelling. I have frequently seen pictures produced by inferior lenses in which the contours of the features appeared to be bounded by outlines as clear and distinct as if they had been drawn by hand with a fine pointed pencil, an effect which has been lauded as the very perfection of sharpness, but which I nevertheless attribute to the want of that very quality. There are certainly no such outlines in nature; on the contrary, the boundary of vision glides gently from our sight, and dies softly away.

In this view of the case I fancy I am supported by one who, unlike myself, speaks not only from his observation of natural objects, but from a scientific knowledge of optics. Mr. Rothwell stated in a recent number of the *British Journal of Photography* that "he had never yet seen a photograph possessing that fine and perfect definition which he wished to see attained."

Sharpness, as at present understood, has never been very popular with our best men. Mr. Sutton, speaking of the wax paper process, said in a recent number of the *Notes* that one of the evils attendant upon the introduction of collodion was that of "exalting the quality of sharpness," and "lowering the appreciation of higher qualities."

Professor Hunt, speaking of this quality, regretted that "intense illumination was so much sought for under the idea of producing the sharpest picture," saying that although many productions were remarkable for this effect it was extremely unnatural, because, "*the human eye never sees this extraordinary sharpness of outline in nature;* upon the edges of every object there are fringes of light, which soften off their outlines, and subdue the general tone of objects, blending all harmoniously." Lake Price warmly denounced "the parrot cry of sharpness," and in short, so have very many others equally eminent. But as I have before said, it is now a question with me whether sharpness or perfect focus is really the quality thus denounced.

Certainly the artists who recommended that the lens be put a little out of focus, made a funny mistake. Sir William Newton was *not* one of these; for, as I have shown, he, in his paper, actually advised that efforts be generally directed to the obtaining "*still more minute and perfect detail;*" and I am, therefore, inclined to believe that his ideas *then* were not unlike those I express *now*. A picture out of focus is certainly blurred at the outlines, but it is not less blurred in its lights and shadows, moreover, it is flat and weak, and altogether a thoroughly inartistic affair. I do not think with Sir William that it would be good even as an artist's private study, and I am certain that while it had lost all worth as a photograph, it would be of no more value as a picture.

I have already referred to the control we have over this quality of sharpness by choice of lens, and method of using it. It is therefore of consequence to settle what part of a subject should be focussed for sharpness.

This question will be answered differently, according to the different ends aimed at. For the architect an equality of sharpness distributed over the whole picture will, of course, be most suitable. But the artist will always desire that every attractive quality of a picture should find its focus where the interest of his performance centres. In a portrait, the head, and those features especially which require the most prominence given to them, will be most illuminated, and most carefully wrought out in their details. In a group the principal figure will receive similar treatment; and in a landscape the vigour and force of chiaroscuro, as well as the expression of minute detail will naturally enough occupy the foreground.

In opposition to this how frequently do we see photographs in which, through the use of a very small diaphragm, the ear and boundary lines of the hair are as sharp and distinct as features which are more important and prominent, or a group, in which we find no more definition secured for the hero of the action represented, than for a figure which acts as the merest accessory to help the story. And in a landscape do we not frequently see that the operator has focussed for the most distant object in his view.

Sharpness should, I therefore venture to assert, be clearly separated from what would be more legitimately called hardness; should be limited in amount; and judiciously secured for that portion of a portrait, landscape, or composition group in which it will have tne most pictorial value as focus. I use the word focus here in its artistic sense.

The painter recognises the value of focus throughout his whole work. To secure breadth of light and shade he obtains a focus of light and a focus of dark, in short, all his effects invariably have their focus. But if the lights were of nearly equal brilliancy all over the surface of his picture, and the darks of nearly equal depth, if no one part of the production was more attractive than another, and an equality of interest pervaded every part of it, if, in short, it had *no focus*, it would be a very poor and miserable affair, devoid of both art and interest. Yet we "stop down" our lenses to the smallest possible aperture, and bring all their powers of focus to bear upon the most distant portions of a view, in order to obtain *no focus*, and so ruin pictorial effect and natural truth. Sharp distances as evidence of depth of focus, are mistakes only to be equalled by "white skies." Why, nearly all the poetry of nature lies in the exquisite sensations of the broad free air, the home of the glorious sunlight, and the boundless dwelling place of the fetterless wind; the ocean of the universe, connecting worlds with worlds, and systems with systems; and we are to shut out this mighty element from our beautiful sun-pictures, are to push back our foregrounds, and drag forward our distances, and crowd them into a little white-washed dungeon for the sake of "sharp distances" and "depth of focus." Truly it wont bear thinking of.

The other day, being with my friend, Mr. Simpson, the editor of the Photographic News, we were examining the effect of stops upon the image on the gronnd-glass. I took my station under the focussing-cloth with my eye fixed on the ground-glass screen, and Mr. Simpson changed stops the while. At every change of aperture beginning with the larger and coming to the smaller, there was a clear distinctive variation in the character of the view, distant objects growing sharper and coming nearer, until at length an almost flat map-like appearance gradually became apparent. *Sharpness was everywhere, focus was nowhere, and space was annihilated.*

If I am not mistaken, Mr. Grubb, in one of the early numbers of the Photographic News, referred to this "effect defective" arising from the use of very small apertures and pointed out, by way of illustration, the images produced by telescopes and microscopes. The moon seen by the full aperture of a telescope is in perfect relief, and the prominences on its surface are seen with their cast shadows and real chiaroscuro; but if the aperture be reduced by a small diaphragm, although sharper, it then becomes a mere flat circle with a map-like surface.

The presence of atmosphere is always recognized by the English painter, while the English photographer's prime desire seems to be to ignore it. There is no better illustration of the effect of atmosphere upon retiring objects, than that of seeing how their colours become affected by it. As the green grass of a field retreats every few yards change in color and tone, partaking more and more of that of the atmosphere. So with form, as veil after veil of thin air interposes between us and the object before us, lights grow less powerful, shadows lose their force, and details disappear, the finer and more delicate first, the stronger and bolder last. Perfect detail, brilliancy of light, and depth of shade, are then qualities which, falling in their right place on the more near and prominent objects, represent sharpness where sharpness should be, and thus give a *focus* to the view. For it must be clear that where all parts are equally sharp there can be no focus.

And so I leave the matter in your hands. I think I shall produce a discussion, and hope I shall benefit by it. It is somewhat bold of me to come forward and tell so many old photographers and scientific men that sharpness isn't sharpness, and focus isn't focus, but I have done it and must dare the consequences. The fact is, I want to know what sharpness is, and have in reality only gone in a somewhat rambling way about making the very simple enquiry chosen for a title to this unpretending little paper. Before commencing an argument, the first best thing you can do, is to define terms; and having omitted this preliminary, the next best thing you can do is to begin again without omitting it. And so I end, as I began, with the short question, *Sharpness—what is it?*

THE SOLAR CAMERA: ITS MANIPULATIONS AND RESULTS.

BY SYDNEY SMYTH.*

Having been invited by our worthy secretary to furnish a paper on the solar camera, we shall with great pleasure "put in an appearance" to his friendly summons, and with your kind permission will read a short record of our manipulation, illustrated by specimens of the various processes we employ, and the negatives we deem best for producing the most satisfactory results.

Before proceeding to the more practical part of our subject, we would beg to say a few words in defence of this really beautiful photographic instrument.

Most of you are doubtless familiar with the various methods of enlargement recommended before the introduction of this instrument, and may have perhaps seen the various clumsy implements contrived to produce the desired results.

We remember on one occasion going into the warehouse of a photographic dealer, and were suddenly brought to a stand by a queer misshapen mass of black timber that seemed to our puzzled eye to be something between a reduced copy of Noah's Ark, and the spout used at the east-end wharves for shooting coal. We asked the shopman what new business they were going to launch into, the thought just vaguely flashing through our mind that some expeditious method of vending coal would be a good hit in a west-end greengrocer's store. For in these go-a-head days,—when the careful housewife can have half-a-crown's worth of brushes, and the youngest of her household cherubs hit off for 2s. 6d.: When the lords of the creation can have a hat, best Paris make, for 10s. 6d., including portrait inside to prevent any awkward cases of mistaken identity: When at delightful Greenwich you can have tea, including shrimps and correct photograph of the happy party all inside of the (h)arbour: or when at Epping Forest, you may have your fortune told, and yourself photographed, to send to the handsome young lady what's got her weight of gold all awaiting for you: When, if the wind be contrary, and you are choked in consequence by the smoke, you may send for the sweep, who will, when you pay him, furnish you with his card, when you will learn that he will be most happy to take your portrait (in carbon of course) for 6d.; When the remembrance of all these mixtures occurred to us, it did not seem impossible that the wholesale dealer might not follow in the steps of the photographic retailer, or rather "headsman," and extend his business in popular photographic ways. The indignant shopman, however, informed us that instrument was for enlarging. We think the solar camera upon the table must strike all present as being at any rate an advance upon the clumsy thing we have described.

The plan mentioned by Mr. Hardwich of putting the negative in a hole in the shutter of a darkened room, and throwing the image through the reversed lens upon a screen, has not been found practicable, except where only a slight enlargement is necessary; for it rarely occurs in practice that the light opposite the window is the light of the sky; in nine cases out of ten, on the contrary, the window will command an uninteresting view of a dead brick wall. The only practical means of employing this method is to place a collodion transparency in the shutter, and instead of paper, put a collodion plate to receive the image. A negative is thus obtained from which copies can be taken. When numbers are required, this plan, however, will be better carried out by the solar camera.

* Read at the meeting of the South London Photographic Society, on the evening of Thursday, May 16th, 1861.

There are many who dispute Mr. Woodward's right to a patent; we are not of the number, for we hold that the successful application of an old principle to a new science is next door to a new invention; and if we grant that the principle is akin to the solar microscope, we do not remember to have seen any record of its successful application to photography. Now the point of originality in Mr. Woodward's instrument, and one which we hold much more worthy a patent than thousands so called, is the exact placing of the lens, at the focal point of the condenser; by this means the rays forming the luminous image travel through the centre of the lens, and are parallel. The resulting image is, in consequence, wonderfully free from spherical aberration, and gives in consequence a picture sharp to the margin. When in the dark room this is clearly seen, for the bright spark on the centre of the lens is seen to be the reduced image of the sun concentrated there. The darkened part of the lens plays no part in the production ot the picture, and may therefore be termed the diaphragm, the aperture being just the size of the sun's image.

We have found that the cleanest prints are produced by direct printing, but this plan is frequently very tedious.

There are not many days in the year when we have the uninterrupted beams of the sun for several hours together. It is in consequence very annoying to start with sunshine, and then have to wait an hour in consequence of the sudden arrival of an express train of heavy clouds. Our favourite plan is to print by development; there is a charm about this plan that far surpasses all the many enchantments of photography. The paper is pinned upon the easel, the sun is turned on much after the fashion of turning on gas, and directly afterwards a dim staining of the paper takes place, gradually assuming form, and appearing, in a few seconds, a ghost outline.

The paper is taken down, the developing solution poured on, and rapidly spread by means of a strip of Canton cotton, and gradually there arises out of the surface of the paper a distinct image which goes on increasing in intensity until all the roundness and solidity of life is apparent. We never tire of this part of the process. The rising up of these large images from the blank surface of the paper, is so like magic, that we feel it fortunate we produce these wonders in the reign of Victoria instead of Elizabeth, for we doubt not we should have been rewarded for our pains by a warm reception.

During the winter months we found that the more bromide we employed up to a certain point the more sensitive the paper became.

The salting solution we then used was prepared as follows:

Chloride ammonium	6 grains
Bromide potassium	9 "
Gelatine	4 grains
Water	1 ounce

With paper thus prepared we obtained pictures in three minutes with average sunlight.

The formula which, after many experiments, we think the best, is

Chloride of magnesium	4½ grains
Bromide of potassium	7½ "
Gelatine	4 "
Water	1 ounce

With this solution No. 1 was produced in three seconds on Towgood's paper. We find that the bromide has a tendency to produce green in the tone of the finished print, on Turner's negative paper. The tint is, however, by no means disagreeable on Towgood's small paper. No. 2 will show how important a part the proportions of the salt play in the tone of the picture—you will see the finished print is much warmer. It was produced by the following salting solution on Towgood's small size paper.

Chloride of ammonium	... ...	9 grains
Bromide of potassium	... ...	3 „
Water	... ...	1 ounce

The silver for the first picture was sixty grains. The second picture was prepared with same solution, but a much larger quantity was brushed on. No. 3, is printed on Saxe paper, as also No. 5, but with silver eighty grains to the ounce. We find that on Saxe and Rive paper there is a tendency to excess of half tone, and the paper is extremely rotten in washing.

We salted this paper with the following preparation:—

Chloride of ammonium	... ...	9 grains
Arrowroot	... ...	4 „
Water	... ...	1 ounce

Sensitized with silver ninety grains to the ounce, and exposed for twenty minutes. It developed very slowly, and when finished was by no means over-exposed.

We brush on all our solutions except the hypo. We use several large plates of thick glass, keeping each for its especial use. The salting solution is brushed on and allowed to remain until the paper lays flat, which, with most paper, is about three minutes. Brush on the silver with Canton cotton, reserving the saturated piece to darken any of the shadows that may need it during development.

When we develop we turn up the edges of the print, so as to form a tray and pour on a saturated solution of gallic acid, with a few drops of acetic acid added; the prints develop cleaner when acetic acid is used. To wash away the gallic acid we use a large quantity of water—this is absolutely necessary, otherwise stains would be produced which would not be removed by the fixing. The fixing solution is of the usual strength, and does not appear to alter the colour of the print. All the operations except salting must be performed in the dark room.

The negatives are not varnished: it is necessary that they be taken on perfect glass, as the slightest scratch is made painfully apparent in the enlarged picture. The great thing to be guarded against in producing the negatives is to avoid intensity—a good positive picture with plenty of half tone is just the thing—they cannot be too sharp, and certainly not too clean.

We believe we have mentioned all the points we deem of importance; should we, however, have omitted anything, or not have made ourselves clear, we shall be glad to answer any questions.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this society was held in St. Peter's School Room, Walworth Road, on the evening of Thursday, May 16th. Mr. SEBASTIAN DAVIS took the chair.

After the minutes had been read, and some fine *carte de visite* portraits presented to the society's portfolio by Mr. Wall,

Mr. SYDNEY SMYTH read a paper on "the Solar Camera, its manipulations and results." (See p. 247.)

Mr. V. BLANCHARD then, at the request of the chairman, pointed out the method of working the different parts of the solar camera, calling attention to one on the table. He also passed round several of the negatives, from which some excellent prints, which were hung round the room, had been produced. The negatives were of various sizes, from quarter to half plate; thin, clean, sharp, and full of detail, having been produced by means of iron development, and a bromo-iodized collodion. The prints were of various sizes, from half the size of life to full life size; some were vignetted and some printed to the edges, all clean and sharp; some soft and detailed; others with less detail and more vigour; some grey in tone and some brown. The whole had been produced by development. The specimens elicited much admiration.

Mr. WALL asked what was the largest size to which the enlargement could be satisfactorily taken.

Mr. BLANCHARD said there was scarcely any limit; up to six feet if necessary. It was only a question of getting paper and other appliances large enough, and of giving longer time. They had some double Saxe paper, but had not yet tried it. The greater the enlargement, the longer the exposure necessary, and the coarser, of course, the effect. He had omitted one point of importance in speaking of the manipulating, that was the necessity of having the focus of the cone of rays, coming through the condenser, on the front lens of the portrait combination, and exactly in the middle of that lens.

Mr. G. WHARTON SIMPSON asked Mr. Blanchard if he or Mr. Smyth had ever tried an ordinary achromatic meniscus lens, instead of the portrait combination; as the focus of the condenser being on the front lens of the combination, the back lens appeared to play little part in the enlargement.

Mr. BLANCHARD said they had not tried that; but it certainly appeared to him that the front lens alone would answer perfectly well. They generally used a half plate portrait combination.

The CHAIRMAN asked if they had ever used the solar camera for the purpose of enlarging negatives.

Mr. BLANCHARD said they had not done so, but it would be a very important application. He thought some of Wilson's glorious instantaneous negatives, enlarged two or three times, say to 12 inches by 10 inches would give magnificent prints. They ought to be enlarged before they were intensified sufficiently for ordinary printing. The best plan would be to take a transparency by superposition on a dry plate, and from that enlarge on to a wet collodion plate of the right size.

Mr. SAMUEL FRY had adopted that plan with great success, and thought prints from an enlarged negative better than those enlarged on to the paper direct.

The CHAIRMAN asked if they had tried the effect of enlarging stereoscopic negatives. If good results could be obtained in enlarging them up to, say, 10in. by 8in. it would be an important and valuable thing. It would materially facilitate and lighten out-door operations if from stereoscopic negatives good prints could be produced three or four times as large.

Mr. BLANCHARD called attention to a view of St. Paul's from the Thames, enlarged from a stereoscopic negative to a size of ten or twelve inches. The negative had not been taken for the purpose, and was much too intense; but he thought it would be admitted that the picture possessed artistic qualities, atmosphere, &c., rarely attained in pictures of that size, taken direct.

Mr. WALL had been very anxious to get some good enlarged pictures for colouring in oil. All he had hitherto seen had struck especially by what he might describe as their "emptiness." He had no doubt from what he now learnt that this emptiness and absence of modelling readily existed in the negatives from which they had been taken. They were faithful transcripts of the originals, but enlarging made their faults more glaring. One of the greatest merits of those now exhibited was their freedom from that defect, and it appeared that the sole difference consisted in having suitable negatives, soft and very full of half-tone. Judging from these specimens it appeared to him that more detail and roundness could be obtained by this method than by other methods of enlarging.

Mr. HOWARD said that like many other amateurs he had often desired to have enlarged prints of some of the best of his small negatives, and had tried his hand at enlarging by the usual method. Although that answered very well within certain limits, they could not exceed an enlargement of two or three times without getting some indistinctness. He usually took a transparency first on a dry plate, by superposition, and then by placing that in the camera and elongating to the proper distance, obtained an enlarged negative. He now exhibited one to the meeting.

Mr. FRY said he preferred to enlarge by that method rather than by the solar camera, because he was not, in using it limited, as in using the solar camera, to one class of negative. In enlarging on to a collodion-plate, it was possible from a hard picture to produce a soft negative, and *vice versâ*. His plan was to get a transparency by superposition, and from that enlarge in the camera on to a large Fothergill plate. He had, at one time, used the solar camera, but he now dispensed with both reflector and condenser, merely allowing the diffused light of the northern sky pass through the transparency. He found the results just as good; and the trouble was less, although the exposure was longer. He had, some little time ago, put this process to a severe test, having enlarged a copy of an oil-painting to 34 inches by 23 inches, from a small negative, the photograph being requested that size to enable a tracing to be made from it on to metal for engraving. Before concluding, he wished to ask Mr. Smyth if he had ever used the ordinary sea salts in preparing his paper for printing by development. As these salts contained all the haloid salts used in photography, he thought there might be an advantage in trying them in their natural combination.

Mr. Smyth had not tried, but had often thought of doing so.

Mr. Blanchard pointed out one defect there was always risk of when the printing required a long time. The paper being placed upon the easel wet began gradually to dry and contract, and sometimes the impression would be blurred, or even doubl , in places from the contraction of the paper during slow printing. In some cases where the enlargement had to be painted, the artist did not like photographic paper, and instead, therefore, of printing a picture, the artist could place his canvas on the easel in focus, and a very few touches of the pencil would secure a likeness more perfect than could have been secured in two or three sittings. A great advantage was secured to the artist by this method.

Mr. Hughes said this was an aid of which artists were getting largely into the habit of availing themselves; but, in that case, they preferred the use of a transparency instead of negative, so that they had light in the place of light, and shadow in the place of shadow, instead of the reverse, as when a negative was used. Where this object only was desired, they were not in the habit of going to the expense of a solar camera, the effect being produced by means of a lamp, magic lantern fashion, and thus they were not at the mercy of the sun. For photographic printing with a solar camera Mr. Fry was the first he had heard who objected to the use of the sun, and preferred diffused light. Every one he had known who had used the apparatus, preferred some intense light, and, if they could not get the sun, tried the electric light, or the oxyhydrogen light, or some such direct source. And it was because there was so little sunlight last summer, so little had been done in enlarging. He was so worn out last year by waiting and watching, up to catch every stray ray of sunlight, that he had not had courage this year to get his solar camera fitted up into working order. The difference between direct sunlight and diffused light in the solar camera was as great as between daylight and moonlight, and as for the brilliancy and distinctness of the image there was no comparison.

Mr. Wall now read his paper, "Sharpness—what is it?" (see p. 244.)

Mr. Hughes could not help thinking Mr. Wall had selected a wrong title for his paper, interesting as it undoubtedly was. The real question they had to consider, he apprehended, was not what is sharpness; but how to use it: when in place and when out of place; how far artists have agreed; and how far photographers have made proper use of their powers. Mr. Wall had stated that photographers were not agreed on the quality; but he thought artists were quite as undetermined. It was as difficult to define a term like sharpness, as it was to define any primitive sensation. They might know perfectly well what it was, but have no words exactly to define it; and thus they were often driven to describe it by what it was not, by its absence rather than by its presence. He might say, look upon the ground glass when you have got an image in focus, and you know what sharpness is, for you will see it. What they saw was sharpness; but how far it was desirable to use that sharpness was another question. Sharpness was very desirable in a razor, but not so in a paper-knife. It was like everything else in this world of ours, it was wrong when out of place. The old adage of the danger of putting sharp tools in the hands of children, really seemed to meet the whole question. Inexperienced and ignorant photographers misused this valuable quality, and defined the brick wall more carefully than the head of a person who stood near it. But was sharpness to be decried on this account? On the contrary, let it be in its proper place, and let them use all their powers, optical and chemical, to secure it in its highest and most exalted condition. What had been hitherto the greatest objection raised to the enlarged pictures of the solar camera? Simply their alleged want of sharpness. It was one of the most important qualities, and they must never neglect it. He would have been glad if the paper had drawn the distinction between sharpness and hardness; had pointed out how the former quality was to be obtained, how it was to be used, and how it might be misused, as all good things might be abused. In portraiture, for instance, they all knew the vital and important part was the eye, the "window of the soul." That was the all-important point for focus. It was a first condition of good portraiture that the eye be sharp. If there were any expression of character or intellect in the face at all, it would shine out there, and thus it became the point for focus. He thought photographers knew this and aimed at this. He did not think they were so wanting in this matter as friend Wall seemed to imagine. They might frequently come short of what they desired, there were many things not under their control; their chemicals would not always register every gradation their lenses would give. It had been more want of means than want of knowledge of what was desirable that had rendered many photographs so hard; but he hoped things were improving in this direction. He was glad Mr. Wall had not endorsed Sir William Newton's plan of turning the lens out of focus. It was no wonder photographers did not sympathize with that notion. If Sir William had spoken of the want of gradation and softness, instead of complaining of excessive sharpness, he would have had the sympathy of both photographers and artists. But still he thought there was a tendency in Mr. Wall's paper to saddle on the back of sharpness the faults of hardness. All photographers were agreed in condemning the latter quality. But they were also agreed in the importance of the former. It was to secure it they gave ten guineas for a lens instead of one guinea. It was a great mistake to attribute the sharp outlines to a bad lens, and the want of outline to a good one. The converse was true; it was one of the common faults of bad lenses that they gave sharpness nowhere, neither in the outline nor any where else. Hard outlines, &c., were more a matter of lighting than anything else, and a lens which gave no definition would never produce a good picture. He wished to be distinctly understood he was not advocating hard outlines; his main object was simply to assert that photographers were not so disagreed as Mr. Wall imagined as to what sharpness was. They knew very well what it was; but a picture might be sharp and soft, or sharp and hard. They required a good lens to give them sharpness, but some of them required to be taught to use it in the right place.

Mr. Howard thought sharpness was a necessity which had arisen of late years, out of the practice which photography had introduced of delineating nature in minute forms. In large paintings it was not required; but in cabinet pictures and miniatures it was more important, and in the photograph most of all. In the early photographs it was a common complaint that one-third of the picture was out of focus; and in pictures so minute as to be examined in the hand, that was a glaring fault. It was true that the human eye could not take in every object in a landscape and see it in focus at one time. If the eye were fixed on an object half a mile off, and then an attempt made at the same time to get something in focus within a few yards, it would be found to be impossible; but still in a picture, the whole of which could be examined at once, bad definition would be a fault. Sharpness, therefore, he considered an absolute necessity in small pictures.

Mr. Eidmanns made some remarks on the difference between the operations and results of the artist and the photographer, the import of which we did not catch.

Mr. Fry thought that this question came very appropriately after the discussion on enlargement. The specimens in the room were, he thought, as sharp as it was possible to produce enlarged pictures, and yet the chief objection to them in the eyes of many would be that they were not quite sharp.

The Chairman would define sharpness as freedom from optical distortion. The amount of sharpness desirable in a picture mainly depended on the distance from the eye it was intended to be placed; and the enlarged pictures before them, when placed at a proper distance from the eye, were as sharp as need be desired. Regarding the practice of photographers, he thought that few would be found who would attempt to focus for the distant parts of a picture.

Mr. Wall, on rising to reply, said he must repeat his conviction that considerable difference of opinion did exist amongst eminent photographers on the subject of sharpness, and excess of that quality condemned. Mr. Sutton said that one of the evils of the introduction of collodion had been the exalting of sharpness to the detriment of other more important qualities. Lake Price had condemned the "parrot cry of sharpness."

Mr. Hughes begged to suggest that Mr. Wall was mistaking the aim and intention of these writers. If one eminent photographer had distinguished himself more than another in insisting on the importance of sharpness it was Lake Price. One of the most important chapters in his book was devoted to the use of stopes, and he had contrived a method to facilitate the insertion of a central diaphragm after focussing; all these things in furtherance of that very quality of sharpness.

After some further conversational discussion.

Mr. Wall resumed. In reference to Mr. Hughes' remark, that it might be ascertained what sharpness was by looking on the ground glass. That would be very little use to a blind-man, and the man whose eye was not educated was literally blind: he was convinced that many photographers did not understand what the quality really was, and they must be taught to see it before they could seize it. Regarding his remark, that sharpness was the quality of a bad lens, he thought he was probably wrong, and Mr. Hughes right, that hardness of outline which he had attributed to the lens was probably due to manipulation and lighting. Regarding Mr. Howard's remark as to sharpness being a necessary quality to small pictures, it was perfectly true that a cabinet picture would be more minutely detailed than a large oil-painting; but each would have its focus of sharpness, in which the chief objects would receive the most perfect definition. Mr. Fry had referred to the pictures of the solar camera as deficient in sharpness, but he, Mr. Wall, thought the pictures before them possessed more perfect gradation and detail than almost any small pictures he had seen. The chairman had doubted whether any man would ever think of focussing on a distant part of a view. Now, he remembered not long ago, in one of the societies, great praise was given to the pictures of a lady because a church, five miles off, was as sharp as the foreground. He still thought more attention should be given to the subject that it might be distinctly understood that hardness was not sharpness.

Mr. Simpson suggested that Mr. Wall might with advantage at some future period devote a paper to the proper place and use of sharpness.

The Chairman announced that the next would be the annual meeting of the society, and that the committee would have several alterations in their rules to propose.

Mr. Hughes referring to this subject begged to suggest that, as a period had come in which it was desirable that the constitution of the society should be remodelled in various points, the committee should take the subject into consideration, and be prepared with their recommendations on the subject in the annual report.

After the usual votes of thanks the proceedings terminated.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 22*nd May*, 1861.

For some time past rumours have circulated of a marvellous application of photography to sculpture, made by a young Belgian artist, François Willême by name, which, in the absence of full particulars, was looked upon with doubt and suspicion, as seeming impossibility was involved in it. Nothing more nor less than the actual production of statues, &c., by the agency of photography, without the aid of the sculptor's hand, was claimed for this new discovery or invention. At first sight this proposal would really seem to involve a contradiction, as two arts, based on entirely different principles and methods, were ostensibly combined in one. For how could it be supposed that by any graphic process whatever a plastic work could be obtained, seeing that one produces its results on a plane surface by means of light and shade, and the other by relief? However, Mr. Willême appears to have solved this singular problem, and the results, pronounced by competent authority to be unexceptionable, are now before the public; and as you have now the details of the process at hand, you can readily judge for yourself whether the applications of photography are not surprisingly and ingeniously enlarged by the genius of Mr. Willême. He claims to have demonstrated that, by the aid of photography, he can produce sculptures from nature, from the living model, from the inert model, from microscopic objects enlarged, sculptures of the same size as the model, or enlarged or diminished, grotesque sculptures, and bas- or alto-relievos.

The Exhibition of the French photography, now open, commands a large share of public attention and admiration. As it is two years since a similar display was made here, the progress of the art in various directions is strikingly apparent. Those who are most anxious and exacting about the artistic element in photography must, I think, be fully satisfied now that there is no fear that photography will be deficient on that score. In portraiture especially, do we find the fullest recognition of the principles of art; the productions of Delessert, Count Aguado, Mayer Frères, Fargier, and others that follow in their wake, are ample vindications of the claims of photography to be ranked among the fine arts. Each year we have thought that the limits of perfection had been reached, and yet this year's productions certainly eclipse all preceding efforts. Portraiture makes much larger demands upon the artistic talent of an operator than either landscape or architecture, for in the latter his chief concern is in a good selection of the point of view; he has no control over nature's chiaroscuro, but in portraiture he must himself create the chiaroscuro; and considering how few among the professors of art themselves truly understand the elements or appreciate the importance of this prime element of art: our surprise at the comparative variety of artistic portraits will soon give way to the surprise induced by meeting with good portraits at all.

Our present Exhibition is exceeding interesting from one feature alone; apart from the many other claims it has upon our consideration, it exhibits specimens of most of the new methods and processes that have been introduced to notice during the past few years. Life-size portraits occupy a very prominent position in the collection, not only on account of their remarkable dimensions, but also by their number and remarkable excellence. M. Edouard Delessert's works would almost form a good exhibition of themselves—he has no less than fifteen portraits and groups, almost all of which are full-length and life-size; among the groups is a pair of ponies, one-third the size of nature! he has also a group of white terriers, which seem instinct with life. But of all his works I most admire a portrait of a lady in black drapery, which is worthy of the pencil of Vandyck.

M. Joly-Granzedor, whose name is new to photographers, comes upon the scene, like a comet, in a blaze of dazzling splendour. No one knows where this master served his apprenticeship, but it was in a good school wherever it may have been. His pictures are representations of ancient and modern statues and bas-reliefs, and are intended to form a museum of the choicest productions of the plastic art.

M. Bertsch, of whose automatic camera you have heard already, and whose studies have thrown so much light upon the principles of the solar camera, exhibits several specimens of enlarged pictures, taken by his two instruments. They fully sustain all that he has claimed for them.

M. Vilette exhibits some enlarged collodion pictures obtained by the agency of the electric light, and transferred to paper by Moitessier's method: it cannot be said that they are at all satisfactory.

M. Poictevin sends some excellent specimens of the results obtained by processes of his invention, as carbon printing, positives on glass in vitrifiable powders. The excellence of these productions bear ample testimony to the value of the persevering and intelligent researches of this veteran in the art.

The specimens exhibited by M. Fargier testify that his method has recently undergone great improvements, and leave little or nothing to be desired in the way of vigour and transparency of the tones, and the brilliancy and purity of the lights.

M. Lafon de Camarsac, whose ingenious processes have been described in your columns, exhibits some very remarkable positives on paper. But his enamels excite the most interest and admiration. These pictures, which have passed through the fiery funace, are unequalled in photographic excellence, both in modelling and delicacy of tone. While the shadows are of perfect transparency, the whites retain all their pristine purity. This application of photography is full of promise.

Of the comparative activity prevailing in photography in different countries we may perhaps venture to draw some conclusions, although their value may be insignificant. The number of works exhibited is 1266. The number of exhibitors is 150, of whom only 25 are foreigners. Of the latter 8 are English, 4 Dutch, 3 Swiss, 2 German, 2 Belgian, 2 Italian, 1 Spanish, 1 Norwegian. Thus it will be seen that England stands numerically at the head of the foreign contributions. Something more might have been expected from Germany, which has been outstripped by phlegmatic Holland.

FORMIC ACID IN THE DEVELOPER.

Sir,—Your Paris Correspondent would seem to imply that the addition of formic acid to the protosulphate of iron developer is a new discovery of M. Ferrier, whereas it is as old as the use of protosulphate of iron itself. Although formerly much employed in this country, it has of late years fallen into disuse, but many good photographers still adhere to it. In the 2nd volume of the *Journal of the Photographic Society*, p. 201 (July, 1855) the following formula for an iron developer is given as the best the writer had ever tried :—

Water	6 ounces,
Common acetic acid	30 minims,
Sulphate of iron	1 drachm,
Formic acid	1 drachm.

And in volume 3 of the same journal, p. 278, I find that Mr. Rodger, of St. Andrews, recommends formic acid with pyrogallic as well as with iron. His formulæ are as follows :—

1. Pyrogallic acid	40 grains,
Water	16½ ounces,
Ordinary spirits of wine	1½ „
Formic acid	2 „
2. Sulphate of iron	2 ounces,
Common water	16½ „
Dissolve, and add spirits of wine	1 ounce,
Formic acid	1½ ounces,
Sulphuric acid	5 drops.

Mr. Rodger says of the preceding pyrogallic developer, that it brings out the details of the deep shadows, which with most other solutions would be entirely lost. He, therefore, prefers it for landscapes, and for portraits of gentlemen, while for female portraiture the iron developer is preferable. This he uses much in the same way as Mr. Lacy, of Ryde, described by you at p. 13 of the present volume, and, like him, intensifies after fixing.

It seems that M. Ferrier has been trying the effect of nitrate of lead in his silver bath, as an accelerating agent, and found (your correspondent does not say how), that it presented the phenomenon of containing formic acid, which was at once pronounced an accelerator, and that Taupenot plates prepared in this bath required only one-third of the ordinary exposure. As this matter is interesting to photographers perhaps your correspondent will favour us with more precise details on the subject.

Whatever may be the merits of M. Ferrier's instantaneous negatives of Paris, he has been anticipated by those of Mr. W. England, the artist of the London Stereoscopic Company, to say nothing of the productions of other artists, English and American.—Yours very truly, R. A. R.

[The use of formic acid in an iron developer is, as our correspondent states, very old, but we do not remember to have heard it described before as an accelerator. We fear that our French brethren are not always in the habit of describing very freely and precisely what they regard as important secrets. The chief interest, we apprehend, attaching to these instantaneous pictures is their extreme sharpness with so many figures in motion.—Ed.]

CORRECTING NITRATE BATHS.

Sir,—It appears from some communications I have received, that my directions for testing organic matter in distilled water, were not sufficiently explicit. If you can spare a corner, perhaps you will be kind enough to insert the following addenda.

It is not necessary to isolate the oxide of silver before using it as a test. The experiment is much simplified by adopting the following plan :—

Dissolve thirty grains of nitrate of silver in an ounce of water, then add a drop or two of liquor potassa, set it by till the insoluble oxide has completely subsided (it must not be filtered).; a drachm of this clear solution is to be added to four or five ounces of the suspected water, and exposed to the sun's rays or a strong light. The depth of colour which it quickly assumes shows the comparative amount of organic matter present; the absence of any tint proving its purity.

Then with respect to making a new bath. Assuming a small quantity of nitrate of potash, perhaps not more than is formed by the insertion of two or three collodionized slates, to be no objection, the organic matter in both the distilled water, and nitrate of silver, may be precipitated, and the free nitric acid neutralized by adding liquor potassa gradually till a permanent precipitate is formed, and exposing it to a strong light previously to its being filtered for use. The addition then of acetic acid brings it into good working order for negatives.

Liquor ammonia may be substituted for liquor potassa: but for inexperienced hands I recommend the latter.—Your obedient servant, Thos. A. Barber.

KEEPING QUALITIES OF PETSCHLER AND MANN'S DRY PROCESS.

Sir,—Perhaps the following brief testimony to the sensitive and keeping qualities of Petschler and Mann's process may not be unacceptable to your readers.

In October last I prepared some stereoscopic plates according to this process; in February I resensitized them by the second washing in plain water, but circumstances prevented my using them. A week since I exposed one by lamplight for ten minutes, and yesterday developed it, getting a transparent positive, not equal to Ferrier's, certainly, but respectably good. I have tried all the dry processes, but have never found one to behave properly under such an accumulation of difficulties. I may add that I have recently tried Hannaford's modification with great success as to cleanness of development, but it appears to me to be slower than the original.—Yours, W. H. Ranking, M.D.

Photographic Notes and Queries.

The Photogen.

Dear Sir,—Having had my attention drawn to a statement from one of your correspondents in the News of the 17th inst., I beg to say that the 300,000 is certainly a mistake; it should be 30,000, and if it should interest any one so far, I shall be happy to show vouchers for the truth of the last numbers. I assure you, sir, I am sorry the error should have crept in, because it must be evident to every one that there is no difficulty in producing first-class pictures by the photogen, and therefore no need of any statement to mislead. I can say with truth that any one with ordinary application and intelligence can produce good pictures by its aid. And can refer with some degree of pride to the successful experiments recently carried out by the practical men forming the management of the North of England Photographic Society, and also to those fine specimens of night photography exhibited at the Crystal Palace, taken by that eminent photographer, M. Garnier, of Guernsey. —Your's truly, John Moule.

Sir,—In your last number a correspondent speaks of a want of public confidence in the night process. In answer, I am happy to state that such has not been the result in my experience. On the contrary, I have often in one night taken above 60 portraits by the photogen; and have even been compelled to turn away business, through having worked myself out of the necessary composition.

I am now bringing the process before the public, at that popular place of resort, the North Woolwich Gardens, where I have not the least doubt of obtaining the same amount of public appreciation which has hitherto attended my labours in the metropolis. I am, sir, yours, T. Ambrose, Photographer.

Talk in the Studio.

APPARATUS FOR ITALY.—We recently referred to a large order for photographic apparatus which had been sent to this country by the new Italian government. We saw the other day at Mr. Ottiwell's a somewhat extensive looking camera which formed part of this order. It was for plates 32 inches by 24 inches, with sliding body extonding from 36 inches to 110 inchos, the focus being adjusted by means of the screw and winch from behind. The stand on which it rests is a framework of about nine feet long by about three feet high, and three feet wide, which is placed on wheels. It appeared altogether a very perfect piece of cabinet work. It was fitted with one of Dallmeyer's triple achromatic lenses made expressly for that size. Another lens and camera of the same description for tho same government was for plate 15 inches by 12 inches, and extended from a focus of 10 inches to 55 inches.

PHOTOGRAPHY IN THE ROYAL ACADEMY OF ARTS.—The position eoloured photographs are to occupy as works of art remains to be defined. Painters deny that thoy have any right to be classified as paintings; and photographers refuse to acknowledge them as photographs. It is frequently urged that they should not be received in photographic exhibitions, and they are rigorously oxcluded from public galleries of paintings. Copy your photograph upon canvas, or paper, by any of the many purely mechanical methods in use, and *then* colour the same, and you have real work of art. Omit this *mechanical process* of copying, and your production is that pariah in the world of art "only a coloured photograph." Under these circumstances wo were extremely amused to hear from *indisputable* authority, that occupying the post of honour "on the line" in this year's Royal Academy Exhibition, there hangs a *coloured photograph*. To say more may not just now be advisable.

PHOTOGRAPHY BY MACHINERY.—Speaking of the American invention we described some time ago, a Lyons newspaper says, a machine has just arrived from America which is capable of printing 4,000 photographic proofs in an hour from the same negative. The paper used is said to be prepared with gelatine, and impregnated with iodine of silver mixed with other substances, which endow it with extraordinary sensibility. It is then rolled on a cylinder, and unrolled, when in the machine, by clockwork, so that each portion remains about a second opposite to the negative which, during the movement of the paper, is covered by a lid worked by the same machinery. The sun's rays are brought to bear upon the original in a concentrated form by means of a powerful lens. The result is said to be that photographs which, by the ordinary process, cost at least 1f. 50c. each, can be produced at the rate of a sou each.

STAINS AND STREAKS.—We have received several communications on the subject of Mr. Thomas's paper, and our own remarks thereon, the latter of which have in all cases received ample corroboration and endorsement. Several correspondents speak of working with perfect immunity from these annoyances in rooms abundantly illuminated with yellow light, and somo where very little care is taken to exclude all stray beams of white light. We would press it upon the attention of our readers, however, that too much attention cannot be given to having a room chemically dark, wherever brilliant and rapid printing negatives are desired. A slight amount of deposit on the shadows, caused by diffused light, often entirely alters the character of a negative, and destroys its brilliancy.

DETERIORATION OF YELLOW GLASS.—A correspondent has called our attention to the deterioration of yellow glass from exposure. Some deep orange which he has used, and which acted perfectly at first, has gradually lost colour, and allows the actinic rays to pass. He describes the respective tints of the glass before and after long exposure, as the latter like a glass of pale sherry and water, and the former like the glass of brandy and water, supplied at a road-side inn. It would be wise on the part of photographers now and then to examine their yellow glass and ascertain if it retains its non-actinic character.

YELLOW CLOTH.—Mr. E. Seelig, one of our correspondents, has sent to us a piece of bright orange woollen-cloth, which he has found useful in tent windows. It appears to us much more likely to answer the photographer's purpose than either yellow calico or yellow tammy, as in both these materials minute holes admit white light, whilst here no trace of white light passes.

To Correspondents.

R. H.—Two grains of the double salt of gold are generally stated to be equivalent to one of chloride of gold. We prefer, however, the use of the chloride. In neither case is there any guarantee against adulteration.

G. W. HALE.—The whole of the pictures forwarded arrived safe, the large ones considerably injured, however, in the post. Your results for 18 months' practice are very satisfactory in every department. The card portraits merely require a better background, and the sitter placed a little further from it, to make them very perfect. The paper stereoscopic is very good indeed, as are also the transparencies. We shall be glad to know your method of developing them, as the tone is very excellent. Of the large pictures, that which has the least pictorial value is the best photograph. The other two are both a little under-exposed. It is a wholesome rule to expose for the deep shadows, and leave the lights to take care of themselves. If your object be to sell any of them, the qualities of all are up to an average market standard; but much will always depend on the interest of the subjects. The transparencies have the most commercial value.

S. F. TREVONRY.—From your description, it would appear that your bath contains organic matter. It is necessary before sunning a bath to neutralize the acid, or render it slightly alkaline. Add a little oxide of silver, and then expose to light. See Mr. Barber's letter in the present number. The method of cleaning your glasses would not cause the solarization. Add a little more bromide to your collodion. After sunning your bath, add a minute trace of nitric acid.

D. HILLS.—We do not know, at present, of either stereoscopic or whole plate camera and lenses for sale second-hand.

J. L. S.—We fear that no mere description of the appearance of yellow glass will be a safe guide as to its resistance of actinic rays. The best plan will, in all cases, be to test it. Pot metal will undoubtedly be better than flashed glass, although where silver is used for producing the colour in flashing we believe a perfectly nonactinic yellow is produced. The glass to which we referred as not admitting actinic rays, was light orange pot metal, supplied by Mettam.

VINDEX.—We know nothing of the circumstances you state, which are certainly not very pleasant. But would it not have been better in making such statements in a "private and confidential" manner to have added your own name? As the matter at present stands, although the statements may be true, they are unauthenticated. An anonymous letter does not prove much.

J. A. S.—As a general rule, a more vigorous negative is desirable for producing good results with alkaline toning than with the old hypo-bath. The gold-toned print you sent would have been much better if it had been printed a little deeper, and if the negative had been a little more vigorous. But the difference in the character of the paper on which the two are printed, is alone sufficient to account for the difference in brilliancy. No. 2, the sulphur-toned print, is on highly albumenized Rive paper; whilst No. 1, the gold-toned print is on slightly albumenized Saxe paper. If you use the No. 2 paper with an alkaline gold bath, and print a little deeper you will, we think, get brilliant prints.

HERBERT OGG.—Communications will reach this gentleman if addressed to him, to the care of Mr. T. B. Thompson, 3, Kingston Russell-place, Oakley square, N. W.

STEREOSCOPIC EXCHANGE CLUB.—Members are informed that the address of Mr. Emil Seelig is at present, 10, Moorgate Street.

PHOS.—We are glad to learn that you find our collodion formula so successful. The stereo print forwarded as specimen is very good indeed. We like the plan of camera printing for transparencies ourselves, its chief difficulty is that it does not always give the same rich vigorous tones as dry plates. We shall have an article on the subject in this or an early number. In the method you describe, you do not appear to have any means of enclosing the negative, so as to exclude all light, but that transmitted through it. Where available, the direct light of the sky would, moreover, be better than the use of a mirror. Where a mirror is used, you can only get just the quantity of light reflected from a part of its surface exactly the size of the negative, whereas when the negative is directed to the sky, a flood of light from all parts of the sky passes through it. The mirror would only be available when you have no opportunity of getting the light of the sky from your room being surrounded by buildings. In that case it would be valuable. Regarding the colouring of photographic transparencies for the magic lantern, the only plan would be to adopt the usual method of colouring transparencies on glass; and we fear the discrepancy between the coarseness of the colouring, and the delicacy of the gradations in the photograph would be painfully apparent when the transparency is enlarged on the screen. We have never seen anything of the kind well done.

X.—We are obliged by your note, which you will see we have referred to in another column.

M. A.—Your print is over-exposed and under developed. Try the collodion of the second maker you name; we will write to you.

W. A. B.—We have not used formic acid in a negative developing solution. We believe it has a slightly reducing action itself, and therefore might act as an accelerator.

J. F.—We have repeatedly recommended fresh starch for mounting photographs. Acid gum or paste will inevitably injure the picture. India-rubber dissolved in benzole may also be used.

J. A. L.—Your printing bath is too weak. See that it is at least 60 grains to the ounce. The old-fashioned printing frame you describe is very inconvenient. The hinged back is indispensable to allow of the print being examined during the progress of printing. You can get that one altered.

W.—You can scarcely complain if your apparatus proves inefficient when you paid an inadequate price for it. Cheapness, or falsely called cheapness, has been the bane of photography.

*** The letters of two or three correspondents arriving just as we are on the eve of going to press, have got mislaid, and cannot be answered, they will oblige us by writing again.

Several articles in type, the letter of our German Correspondent, and several others, stand over for lack of space.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, PATERNOSTER-ROW.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 143.—*May* 31, 1861.

PHOTOGRAPHY AND THE EXHIBITION OF 1862.

The Council of the Photographic Society have received from Her Majesty's Commissioners for the International Exhibition of 1862, an answer to the letter of the Chief Baron, the President of the Society, which we published in a recent number, protesting against the classification of photography amongst machinery and the mechanical arts. This answer, we regret to state, is not of a satisfactory character. The Commissioners either really or wilfully misunderstand the claims of photographers as stated in the Chief Baron's letter. Entirely ignoring the claim made for photographs to rank as works of fine art, they state that they are perfectly willing to allot a distinct department to photographic apparatus and photographs, in which such distinction or division may be made between the latter and the former, as the representatives of the Society may think desirable. The confusion between the tools of the art and the productions of the artist, is still maintained in the language of the Commissioners. Such a compromise was resolved not to be accepted by the Council of the Society. The Chief Baron has again written to the Commissioners, re-stating emphatically the claims of photographs to be regarded as works of fine art, and as something essentially distinct and different from the apparatus and mechanical appliances used in producing them. The letter also suggests to the Commissioners the propriety of appointing an occasion on which a deputation of the Society shall meet them, and thus explain and enforce, orally, the claims he makes in his written communication.

We commend the dignified attitude the Council of the Society are maintaining in this matter, and trust that it will be crowned with the success it deserves.

THE SOLAR CAMERA.

The possibility of enlarging photographs, and producing pictures of life-size has always been familiar to experienced photographers, the process being merely a reversal of ordinary operations, and thus instead of producing a small negative from a luminous object of life-size, producing an image of life-size from a small negative rendered luminous by the transmission of light. There have been two methods of enlarging practised: the first and simplest, that which we have just indicated, in which a negative is placed in the camera, and the light passing through it, an enlarged image has been projected on to a sheet of calotype paper, placed on a screen in focus, and after sufficient exposure the production of the picture completed by development. The second process although not so simple or direct has been more generally practised, and has been regarded as easier and more efficient. It consists in getting an enlarged negative by means of two operations. A transmitted, or transparent, positive on glass has first been produced from the negative to be enlarged, either by superposition, or printing in the camera; and from this transparency an enlarged negative has been produced on a collodion plate by the method we first referred to, and from this the enlarged prints have been produced.

From whatever cause neither of these methods have been practised to any great extent. The processes have been too troublesome, or the results have not been sufficiently good. Probably both causes have had their influence. Some two or three years ago, however, an immense revolution in the art of enlarging was announced, and immense improvement in the method of manipulation, and the result was promised. Mr. Woodward, an American gentleman, a portrait painter, we believe, had invented an arrangement for enlarging, which he called a solar camera. It was in point of fact an adaptation to photography of the principle of the solar microscope. The enlarging appliances were an ordinary enlarging camera with portrait lens, and sliding frame for the negative; but instead of pointing the negative to the zenith, or the northern sky, a powerful plano-convex condenser was attached, and a mirror with an arrangement for placing it at any angle, and also making it revolve round the condenser. By means of the mirror the image of the sun was thrown on the condenser, and by it passed through the negative and brought to a focus on the enlarging lens.

The enlarged pictures produced by these appliances were said to be amazingly perfect, and free from the objections which had usually attached to large pictures. They were well defined, delicate, full of modelling, and free from distortion even when the enlarging was carried to an enormous extent. The prints were more brilliant as they were produced by actual sun printing in a comparatively short time, without the aid of development.

We have been for some time past patiently watching the development of this enlarging process which promised so much. The means appeared to us very inadequate to the results promised. We saw no new optical appliances to effect the wondrous improvement. It was simply the old method of enlargment with facilities for better lighting the negative. The information on the subject has been very scanty and meagre, nobody seemed to have an idea upon what occult influences the improved results depended. Some of our French scientific neighbours, who took up the matter warmly, soon got themselves into a complete state of mystification and tangle by endeavouring to devise theories on the subject. The specimens were scarce; but what we did see, although taken under unfavourable circumstances, were full of promise, and showed an absolute improvement upon any we had seen produced by the old methods. Since the invention has been before the public, the weather has been singularly unpropitious, and thus it is we presume so little has hitherto been done in the matter.

As we conceive the question of efficient enlargement to be a very important one, we were glad to see the subject brought forward at the recent meeting of the South London Society, by Messrs. Smyth and Blanchard, and illustrated by a number of enlarged specimens. All of these were good, and many of them of very high excellence. There was nothing offensively coarse in the result of the enlargement; the pictures were round and well-modelled, perfectly defined, and satisfactory in their general effect, eliciting the admiration and commendation of all who saw them.

The results, then, are superior to those produced by former methods. To what is this superiority due? Until we saw the solar camera in operation we could not understand. We have said before that superior lighting facilities appeared to be the only addition to the ordinary method. It *is* to superior lighting the results are due; but how much superior! We know of nothing in photography more pleasing and unexpected, than the first sight of the exquisitely brilliant image of a good negative, as projected on the screen by means of the solar camera. It is to this brilliant lighting, which registers so perfectly, and with such force, every delicate tone in the negative, and to the selection of proper negatives that the improved results are due. The negatives must be perfect; the glass on which it is taken must have no flaws; the film must be even and without structure; the image must be perfectly sharp and well-defined throughout; it should be full of soft gradation, without much intensity, no patches of light, possessing detail and drawing in the shadows, but no foggy deposit over them; it must be free from the slightest spot or stain; and it must be unvarnished.

Regarding many points of the working of the instrument, as we have said before, much mystification has prevailed. The instructions have been precise to the effect that the focus of the condenser should be on the front lens of the portrait combination used for enlarging; but why this should be so has not been stated, or why a portrait combination should be used at all. The sole object of having the focus of the condenser on the front lens appears to be to produce the effect of a small stop so far in front of the lens which is forming the image, and which is in this case the back lens of the combination, and thus produce a flat field. The chief part the front lens in the combination plays, in this case, is simply that of a diaphragm, whilst the back lens, undoubtedly not the best for the purpose, enlarges the image. A simple view lens would, we imagine, answer the purpose better. We suggested to Mr. Blanchard the other day the substitution of the front lens only of his portrait combination; he at once tried the experiment, which resulted in a finer image on the screen. In taking large heads, or vignette pictures, a flat field is of comparatively little moment; but if landscapes, or full-length figures be enlarged, it becomes an important point. In such cases we imagine the use of a triple achromatic lens, with the focus of the condenser on the central lens in the combination, would be the best for the purpose. We think in any case decided improvement may be made in the present practice.

One remark here as to the necessity of the sun. Without absolute sun-light there is no use for a solar camera; the reflector and condenser are much better dispensed with when there is no sun. Without a direct source of light there is nothing to condense, and the negative is better illuminated by presenting it direct to the sky, when diffused light only can be obtained. A few minutes thought, or a single experiment will render this so obvious, that it is unnecessary to dwell upon it.

As regards the chemical part of the operation, the idea of sun-printing is, we believe, almost, if not entirely, given up. The necessity of uninterrupted sunshine for a period varying from one to several hours, is alone an immense difficulty; but when it is remembered in addition, that the earth does not stand still during that time, but continues its revolution, and the only means of adjusting the instrument so as to prevent the shifting of the image by the varied position of the sun in relation to the condenser, is by means of a hand adjustment of the mirror, it will be seen that the difficulties are well nigh insurmountable. Fortunately, however, excellent results are to be obtained by means of development. The chief questions open at present appears to be as to the best means of keeping the image on the surface of the paper, and of securing a satisfactory tone. As regards the former, all the appliances available in sun-printing are at command. That at present most used in sun-printing, the application of a surface of albumen, appears least suitable for development printing; whilst the various substances, such as gelatine, arrow-root, Iceland moss, gum tragacanth, &c., all answer the purpose more or less perfectly. The last substance, proposed originally for sun-printing by Mr. Shadbolt, seems to possess many qualities well suited to the purpose. Some of the best toned and most vigorous enlarged prints we have seen, have been prepared with this substance by Messrs. Smyth and Blanchard, from whom we hope to receive some further details of their working, as experience suggests improvements. The tone and vigour of the image are both much affected by the salts used in preparing the paper. Varied combinations of the different haloid salts are now used, and it appears somewhat difficult to adopt a standard and say, "this is best." Varied proportions must be used with different papers and for different subjects. Indeed, as Mr. Blanchard remarked to us the other day, the successful solar camera printer will learn to study the character of his negatives, and adopt slightly different formulæ, as well as modified manipulations, for each. Without such attention, weak, sunken, and poor, or hard and flat images will be more common than good pictures.

One word as to the patent. We have repeatedly been asked the question, in what did the patent consist, and how far might photographers manufacture similar enlarging cameras for their own use. We are unable to answer the latter of these questions with certainty; but we may make one or two remarks to assist our readers in forming their own judgment. As regards the former, the words of the specification before us are: "I wish it to be understood that I do not claim the photographic camera obscura, or the solar reflector and lens, or any part thereof of themselves; but what I claim as new under the above in part recited letters patent, is adapting to the photographing camera, a lens and reflector in rear of the object glass, in such manner that the instrument may be made to answer the two-fold purpose of a camera obscura, and a camera lucida, substantially as and for the purpose herein specified." Now there can be no doubt but the new application of an old principle may become properly enough the subject of a patent. The question here is as to the novelty of the application. The reflector and condenser are parts of the solar microscope, and the use of this for photographic purposes was amongst the first photographic experiments. In the *Journal of the Royal Institution* for 1802, Mr. Wedgwood describes his photographic experiments with a solar microscope. The earliest operations of the Rev. Mr. Reade and Mr. Fox Talbot, were with the same instrument.

How far these facts affect the question of the present patent, we are not in a position to state. The instrument in its present state is somewhat clumsy and expensive, and thus offers great temptation to disregard the patent. Some of the condensers are full of striæ, which is a serious imperfection; they should be made of optical glass to be entirely efficient. For sun-printing the mirror should be attached to a heliostat to follow accurately the motion of the earth. Various imitations have been made both in America and on the Continent. An American journal now before us announces one, as efficient as the most costly, for twenty-five dollars, or about £5. How far these imitations effect the patent, or how far they are efficient, we cannot tell; we believe the holder of the patent in this country paid Mr. Woodward a good round sum for the right to make and sell, and we should be sorry for him to lose his money. The best protection against piracies is, at all times, to make an article so efficient in operation, and so moderate in price as to render imitations worthless and unnecessary.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Combine.—When the parts of your production have that harmonious connection, or unity, essential to pictorial effect they are said to *combine* well.

Confused.—The eye always requires that some portion of the picture should be devoted to repose. When this rule is not observed, or the component parts of the work do not *combine*, the spectator's eye speedily grows perplexed and wearied, when the picture is said to be *confused*. A portrait, with attractive accessories too forcibly defined; a landscape in which the source, or sources, of illumination are not easily detected; or a group of many figures in which each assumes equal importance, will easily produce this ill effect; although by skilful management it may be avoided. For instance, in the portrait, by a judicious casting of shadows, and arrangement of focus; in the landscape, by a change of position or the choice of a more favourable hour of the day;

and in the group—supposing the figures, as portraits, must each be rendered with equal care and prominence, by introducing furniture, or subordinate figures, which, acting as accessories, may serve to give breadth and unity to the larger, and more important group; for it does not follow that because a subject is crowded, therefore it must be *confused.*

Continuity.—The proper combinations of parts or unity of a picture is also accomplished by the law of continuity of which Ruskin says, "Another important and pleasurable way of expressing unity, is by giving some orderly succession to a number of objects more or less similar," adding, "If there be no change at all in the shape or size of the objects there is no continuity; there is only repetition—monotony."

Contour.—The actual shape or the ideal line indicated by position.

Contrast.—Nothing is more valuable to the artist than contrast; from it he derives his greatest power, and his most striking effects. To quote again from Ruskin, who says, in "The Elements of Drawing," that "the character of everything is best manifested by contrast. Rest can only be enjoyed after labour: sound, to be heard clearly, must rise out of silence; light is exhibited by darkness, darkness by light; and so on in all things. * * * Every form and line may be made more striking to the eye by an opponent form or line near them; a curved line is set off by a straight one, a massive form by a slight one, and so on; and, in all good work, nearly double the value, which any given colour or form would have uncombined, is given to each by contrast; * * * but great painters do not commonly, or very visibly admit violent contrasts. They introduce it by stealth, and with intermediate links of tender change; allowing, indeed, the opposition to tell upon the mind as a surprise, but not as a shock." Circumstances may, however, arise in which even the most forcible of contrasts may be essential; but, as a rule, that art is best which best conceals the tools with which it is worked, and the photographer, if he does not seek the soot and whitewash order of production, and produces nature's truth of gradation, will very seldom, if ever, err on the score of too violent contrast.

Delicacy.—A quality expressed by beauty of gradation, and the absence of violent contrasts in light and shade.

Demi-tints.—Half tints separating yet uniting the lights and shadows. The extreme delicacy of some must render them frequently lost in negatives by careless development. To aid in their preservation, as much yellow light should be admitted into the dark-room as may be consistent with preserving the plate from actinic influence; and the development should be carried on with extreme caution. It is impossible in a very dark developing room to detect the more subtle gradations of tone which come and go in so short a time under the action of your developer.

Disposition.—The particular arrangement of the parts which constitute the whole; not, however, in the same sense as we infer by *composition* which is held to have a more spiritual significance. We speak—for instance—of the disposition of the drapery, or the accessories, &c., but not of the composition of the accessories or of the drapery.

Distribution.—A word which may possess some peculiar shade in its difference of meaning from that of *disposition*, but which difference I, nevertheless, certainly can't define.

Diversity.—Variety and contrast are essential to a picture, and may produce a very pleasing effect called *diversity*, which should always be so far apparent in your work as to destroy monotony without producing that which I have pointed out under the term *confused.*

Dryness.—A quality the photographer will, perhaps, best recognise as hardness, although I have too frequently heard it called sharpness by the inartistic.

Effect.—That portion of your picture which first and at once challenges attention, should be the effect of the whole. Of course this effect may find its focus in any part of the picture; but to that point all the rest should be subordinate, minor effects, however numerous, merely assisting the *one* effect, which is—par excellence—*the* effect of your picture. Every fragment of the work may have its due and particular effect; we may speak of a fine effect of light and shade, of colour, atmosphere, action, &c., &c., &c., but all such should be treated only with reference to the production of an effective whole.

Feeble.—A term which may be applied either to the conception, execution, or general effect of a picture. A want of vigour in the negative, producing a poor, tame, flat, and weak picture would be, in the photograph, the same which would be called *feebleness* in the picture.

Feeling.—The full meaning of this word can only be thoroughly appreciated by the artist. The painter artist—there are plenty of painters who are not artists, as there are artists who are not painters—has certain instinctive feelings associated with every surface, and every object he expresses. Watch him at his work, and you will see the expression vary as he moves from one portion of the canvas to another; now the lower eyelid swells, and a soft, tender, expression steals over the face; now the thought-laden brows draw nearer, while the wrinkles ripple over the before calm brow; and, presently a stern resolute air calls attention to the more firmly griped brush and more vigorous touches. These indicate that instinctive play of feeling to which so much is due in the finished work. The term *feeling*, however, not only indicates the mental emotion embodied direct from the artist, but also the feelings it conveys to the mind of the spectator. Again, it may be that one portion only of a picture displays this quality. Thus, we may say that such a work displays fine *feeling* for such a quality, but that other parts are deficient in *feeling*. In photography this is also the case. One photographer has a fine feeling for the depth, transparency, and lustrous surface of water, another for the expression of foliage in all its beautiful varieties, and another excels in the *feeling* with which he endows the sombre grey ruins, and crumbling relics of olden times. Such a quality then exists in the photograph as palpably as in the painting, and to its cultivation, by indefatigable study of nature and art, the photographer should earnestly devote himself. When such feelings as originate it come, they bring with them a world of fairy pleasures, which alone are a rich reward for "the wooing o' 'it." An old friend of mine, whose paintings had certain very prominent peculiarities in the days when his miniatures were in repute, some few years since practised photography. When I saw his productions I was amazed to find his photographic miniatures were the exact counterparts of his ivory miniatures; although the latter had qualities you would hardly look for in the former, and the former were, as the catalogues say, "untouched." I could point out several instances in which the peculiar feelings of the artist were prominent in both photographs and paintings produced by the same hand, and our photographic exhibitions will bear me out in asserting that the distinctive characteristics of the photographs they contain are almost as numerous as the exhibitors themselves.

Scientific Gossip.

WE have on several occasions drawn our readers' attention to the important subject of the spectra of artificial light, and while most other journals have been at great pains to give all the credit of the recent spectrum *revivals*—we can hardly call them discoveries—to two German philosophers, we have felt it our duty to claim for our own countrymen the higher merit of having first explored these new fields of scientific research. Not that we wish to deprive MM. Bunsen and Kirchhoff of any fraction of the credit which is due to them. They deserve all praise for the perseverance and philosophical acumen which they have displayed in working out this difficult subject; but when a search through the standard scientific works to be met with in every good library would have shown that all which has recently come to us from the Continent as new was ten or fifteen years ago taken up, thoroughly investigated, and published in England, we think that some censure is deserved by those writers and scientific men who are now holding MM. Bunsen and Kirchhoff up to public admiration, without giving the slightest hint that *all* which these physicists have recently published has been previously made public by Talbot, Wheatstone, and Miller.

Of the labours of Talbot and Wheatstone, in this department of science, we have already spoken; of those of the latter physicist we now propose to allude. At the meeting of the British Association, held at Cambridge in the year 1845, Dr. W. A. Miller, Professor of Chemistry in King's College, read a paper entitled "Experiments and Observations on some cases of lines in the Prismatic Spectrum produced by the passage of light through coloured vapours and gases, and from certain coloured flames." The first part of this paper is devoted to an examination of the prismatic spectra of light that has been transmitted through various coloured vapours aud gases. Some of the results here obtained are unsurpassed iu interest by anything which has been more recently published on the same subject. Speaking of the remarkable, but now well-ascertained fact, that in the light of the afternoon and evening, lines become visible which at other times are not readily detected, the author relates the following curious circumstance. He was examining the spectrum of the diffused daylight towards the evening, when a violent thunder shower came on; immediately lines not before visible became distinctly apparent, and a group in the brightest part of the spectrum, betweeu D and E, though nearer to the former line, became very evident, increasiug in distinctness with the violence of the shower; as the rain passed away they again faded and disappeared. This observation will remind our readers of the remarkable results published by Professor C. Piazzi Smyth, in the Report on his Teneriffe Astronomical Experiment, a full account of which appeared in some of the early numbers of the Photographic News. In these observations on the solar spectra mention is made on several occasions of a line between D and E, which came into view as the sun got low on the horizon, and appeared to "grow" before the eyes of the observer as the light passed through a greater length of atmosphere.

The general impression has been that this growiug line, drawings of which are given by Professor Smyth in different stages of its development, is due to the absorptive action of the atmosphere. Dr. Miller's observation seems, however, to prove that it is caused by aqueous vapour. Several other beautiful results are also given, but although these are very valuable from a chemical point of view, they are not of such immediate interest as those described in the second part, where Dr. Miller treats of his experiments on coloured flames. An alcoholic solution of the compound under examination was made, and this was burnt in a spirit lamp by means of a cotton wick. The lamp was placed opposite the slit iu a tin box, the side of which, next the slit, was permanently open, whilst the opposite side was furnished with a door opening upwards and outwards, so that by a string it could be raised to admit the light of day, and would afterwards close by its own weight when allowed to fall back, Fraunhofer's lines thus served as points of comparison. In this manner the spectra of several metals were examined, and drawings of them given; and our readers will perhaps be surprised to hear that after making allowance for the imperfect state of chromolithography sixteen years ago, Professor Miller's diagrams are *more accurate* in several respects than the coloured spectra figured in recent numbers of the scientific periodicals. In corroboration of this we need only refer to the drawing of the calcium spectrum as given by Professor Miller. In it is prominently given the dark blue or indigo line, which has not been noticed by Bunsen and Kirchhoff. In the description of the calcium spectrum the author likewise states that in addition to the other lines there is a very bright streak in the indigo. A curious circumstance is connected with this blue line of calcium. Two of our most expert and rising young chemists having examined the residues left by some deep well water upon boiling, found, when this deposit was properly introduced into the spectrum apparatus, that, in addition to the well known red and green lines due to calcium, there sometimes appeared a bright blue liue. Upon referring to the coloured maps of artificial spectra given by MM. Bunsen and Kirchhoff to accompany their elaborate memoir on the subject, no trace of such a line was perceived as being given by any of the metals. This being the case, they considered themselves justified in announcing that a new element of the calcium group of metals existed, the characteristic test of which was the production of a bright line in the blue part of the spectrum. Immediately upon the publication of this another chemist showed them that this blue line was not due to a new element, but that it was a normal constituent of the calcium spectrum, which had been in the most unaccountable manner overlooked by MM. Bunsen and Kirchhoff. So far nothing extraordinary is noticeable. One chemist is led astray by an erroneous map, whilst another points out that the map is not to be relied upon, and corrects the error. It is, however, very singular that in Dr. Miller's maps, published sixteen years ago, this line should have been properly pourtrayed, and it is still more strange that it should have been first published in one of the volumes of the *Philosophical Magazine*, the same journal which last year gave to the English public the first account of the recent labours of the Continental savans. We frequently hear of the rediscovery of old facts, but for the same journal to give in an early number an elaborate and illustrated memoir on an important subject; and then, in a subsequent number, to give, with all the honours due only to absolute originality, merely a less perfect edition of the former researches, is an occurrence almost without a parallel in the annals of scientific literature.

The new element, whose discovery by means of the spectrum was recently announced in these columns, has received the name of *Thallium* (a budding twig) as the green line which it communicates to the spectrum recalls vividly the beautiful green tint of young vegetation. Traces of the new body have been found in several specimens of native sulphur. What is supposed to be the element itself has also been separated by the discoverer, Mr. Crookes, in the form of a heavy black powder. A portion of this, so minute as to be almost imperceptible to the naked eye, introduced into the blue gas flame of the spectrum apparatus, gives rise to a green line of extraordinary purity and intensity, a piece the size of a small pin's head being most dazzling, and quite equal to the soda line in brilliancy.

PHOTO-SCULPTURE.

Photo-Sculpture is the name given to a new art invented by a young Belgian sculptor, M. François Willême, the nature of which may be imagined by the word employed to designate it. In the strict sense of the term it is a completely mechanical sculpture, effected without the aid of the hands or chisel of an artist, which, by the agency of photography, any one can execute without knowing how to draw or carve.

This apparent contradiction would seem to be a mystery without the explanation afforded by the inventor, but with this before us, we perceive very clearly that it is not, as might be supposed, an application of photography in which an image of an object is reproduced by a sculptor. M. Willême takes a sufficient number of photographs of the living or inert model, at given points of view, and combining these photographs, and tracing the contours in determined conditions with the first of the points of a pantagraph, obtains by means of the second points of the pantagraph on a mass of modelling clay a statue in relief exactly similar to the model of the same, or of larger or smaller dimensions, in any proportion required. We do not say that the execution of this process is easy, yet with sufficient dexterity it will doubtless become, sooner or later a practical operation to any one accustomed to artistic manipulations, or the technics of the plastic art. The following is M. Willême's method of operating. He places the model in the centre of a circular platform upon which are arranged a sufficient number of objectives of equal power, focus, &c., and placed at the same level, or upon which a camera can be made to traverse in a circle round the model, and in this manner several different views are taken. For simplicity sake we will suppose these photographs to be only four in number, taken, in relation to each other, at 90 degrees apart, and giving, 1st, A, the face; 2nd, B, the right profile; 3rd, C, the back; and the 4th, D, the left profile. The plastic material, hard or soft, but which we will suppose to be soft, is placed on a platform, the circumference of which is divided into as many equal parts as there have been different photographs taken, in the case under consideration, these will be four in number. Two equi-distant tablets, placed vertically, but in planes rectangular or perpendicular to each other, carry—one, the view A, of the face; the other the right profile, B. For these two photographs to be identically and symmetrically placed, the tablets, as well as the photographs, are divided by a double system of horizontal and vertical lines which render the centring and the orientation easy. The two points of a first pantograph are now applied; the one upon the photograph A, of which it follows all the contours; the other upon the soft mass which it cuts into gradually so as to trace a *silhouette*, which is the faithful copy of the silhouette given by the photograph A; a second pantograph at right angles with the first, the point of which follows the photograph B, and the other point of which acts upon the block of soft clay, produces the exact silhouette of the right profile. At the same time, the second points of the two other rectangular pantographs, the first points of which are guided in the same manner by the photographs C and D, design upon the block the silhouettes of the back and left profile. Evidently four silhouettes will not suffice to effect the complete reproduction of the model; the block of clay, after these four operations, will still remain an unformed block; but there is nothing to prevent eight, twelve, fifteen, four-and-twenty or more photographs being taken, instead of four only; a number, in fact, necessary for the reproduction of the external contours in a sufficiently continuous manner, for only a few small protuberances to remain, which may be removed by the hand. In any case, the number of images will be divisible by four; twenty-four is a very convenient number, and quite sufficient; each of the photographs will be numbered in order, from 1 to 24. The turning platform bearing the block of clay will also be divided into twenty-four parts; the photographs upon which the two pantographs act simultaneously will be such as have been taken at a right angle, or at 90 degrees from each other; 1 and 7; 2 and 8; 3 and 9; up to 6 and 24, and every time the tablets received a fresh proof the platform will be turned one division.

But this series of four-and-twenty operations gives only the exernal contours, and the statue will not be complete until the interior contours of the ears, nostrils, &c., are produced. M. Willême obtains these in making the points of the pantograph follow, not only the profiles, but the lines of the light and shade which depict these reliefs and hollows.

The principle of the operations of photo-sculpture being established, its various applications may next be taken into consideration. If the photographic images be taken on some elastic material, as caoutchouc, for instance, deformed or caricature sculptures may be produced; again, by the aid of the electric light, the shadows of a model may be thrown on the tablets on which the photographic proofs are placed, and the latter dispensed with.

Or, according to an ingenious suggestion of the Abbé Moigno, Mr. Willême's photo-sculpture may be attained by a variation in the method above described. Imagine a statue placed vertically, and suppose that through the vertical and central axis of the statue we pass a series of planes, also vertical; each of these planes will cut the statue through one of its silhouettes; the total of these silhouettes constitute precisely the entire contour on the whole of the external forms of the statue. By virtue of the law of continuity it will not be necessary, in order to reconstruct the statue, to have an indefinite number of all these silhouettes, it will suffice to have a certain number of them, forty-eight, for example.

Being in possession of these forty-eight silhouettes, nothing can be more easy, taking them as patterns, than to reproduce the statue. We may also, without difficulty, perceive, that in cutting some planks with a continuous saw (following the silhouettes), the contours of which will be precisely like those of the outlines taken from the statue by the forty-eight sections through the axis; that in grouping and glueing these forty-eight planks around a vertical axis, we shall mechanically reproduce the statue. The continuous saw permits also of our obtaining forty-eight blocks of wood, which in their entire thickness represent these forty-eight silhouettes; and a common saw suffices to divide these blocks into a great number of planks, fifty for example, all bearing the same profile. Hence the simultaneous automatic reproduction of the fifty copies of the original statue.

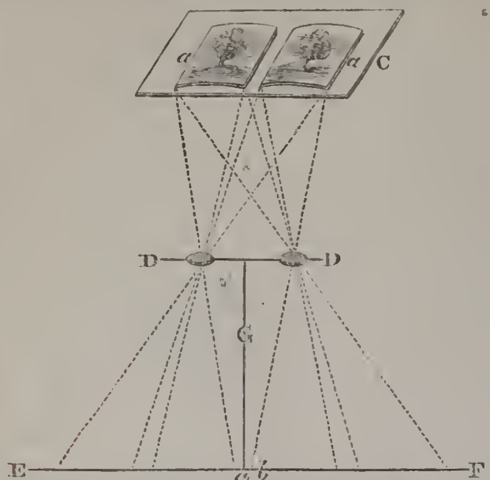
When we consider that these silhouettes, which we can obtain by the saw only from an inert material, photography can supply without difficulty, even from the living model, then photo-sculpture will not appear a visionary affair. In fact, this new mode of mechanical and automatic sculpture is completely realized. Mr. Willême has exhibited a charming statue in wood. obtained by his process, which he can multiply indefinitely, and which a very skilful and critical sculptor pronounces perfect.

STEREOGRAPHS ON GLASS.

BY COLEMAN SELLERS.

TRANSPARENT glass pictures have usually been produced by contact printing on dry collodion plates, and, to bring the pictures in proper position, negatives taken with a binocular camera are cut apart and reversed. This plan has many objections, and few amateurs have been successful in the production of transparent proofs. A decided improvement has been the introduction of the camera and the substitution of the wet collodion plate for the dry one. As so little has been written on this subject, I feel emboldened to offer to your readers a plain statement of a process which has enabled me to make glass pictures more rapidly than I can print on paper. The instrument I use for the purpose is a pair of Jamin lenses, mounted on a bellows camera, which has a slide for vertical adjustment in front, and slides moving horizontally to adjust the lenses to or from each other sideways. My lenses have the view-attachment, and out-door pictures are taken with this attachment in preference to using the portrait combination with small diaphragm. I have made a rough box, which, added to the bellows-box, enables me to draw out to fourteen inches from the tubes to the focussing glass. I have also arranged a board, about four feet long and two inches wider than the camera box, having cleats nailed along its edges to form a track to slide the camera backward and forward. At tho end of this board is nailed an upright board, having an opening made in it large enough to receive a stereoscopic negative, with little buttons to hold it firmly in its place. To understand how this apparatus is to be used, it is necessary to bear in mind that all combinations of convex lenses in cameras have the property of inverting the image, and not only turning it upside down, but reversing it sideways as well.

Referring to the annexed diagram, in which *C* represents a negative taken with a binoclar camera, and the prints from which, to be viewed stereoscopically, must be cut apart and reversed; that is, the lines *a* and *b* be brought next to one another. *DD* are the two lenses of the binocular camera, *G* the diaphragm in the box, and the line *EF* represents the focussing glass. If, now, light transmitted through the negative be made to pass through the two lenses to the ground-glass, the two pictures will be found to



be reversed, and an examination of the dotted lines will show that in the produced image the lines *a* and *b* will have taken their place next to each other, and from the uncut negative will be produced an image on the focussing glass ready for the stereoscope. If the lenses are moved sideways, the images can be made to approach or recede from each other, and can thus be properly spaced on the glass.

Having thus arranged the apparatus, it is only necessary to place the negative end of this box next an open window, and pointed towards a clear sky; the space between the upright board holding the negative and the camera box should be covered in with black cloth, to exclude all rays except those that pass through the negative. If the negative be placed with the film side away from the camera, a picture will be produced that must be viewed from the glass side of the plate, and which, backed with a ground-glass and bound around its edges, is ready for the stereoscope; while, if the collodion side of the negative is turned towards the camera, the picture will have to be viewed with the film side next to the observer. Two vertical lines can be drawn with a lead pencil on the focussing glass, about two inches and seven-eighths apart, corresponding to the centres of the two pictures; these are to help in spacing the pictures.

Thus, if it be a portrait that is being produced, let the nose, or some other feature, be cut by the line in the same manner in each picture; this will, of course, bring them two inches and seven-eighths apart. The size of the picture can be regulated by the distance the tubes are placed from the negative and the length of the camera box. It need scarcely be observed that, having a satisfactory image on the focussing plate, it remains only to substitute a wet collodion plate precisely as if an ordinary picture was to be taken. Length of exposure will depend upon the intensity of the negative, amount of light, and the kind of tubes used. I use my portrait-combination for this copying purpose, slipping a paper diaphragm with a five-eighth aperture in front of the object-lens of each.

The picture produced should be cleared with cyanide in preference to hyposulphite of soda, and toned with a solution of bichloride of mercury in water, and then coated with albumen prepared as for a Fothergill plate; this serves as a varnish and secures the film from cracking up in drying.

The chief advantage to be derived from this process of making glass stereographs is, that as soon as a negative has been taken and dried, it can, without any danger of scratching it, be placed in the copying box as above described, and, when once focussed, as many pictures can be made from it as you please; and, as rapidly as you can flow, sensitize your plates and expose them. — *Humphrey's Journal.*

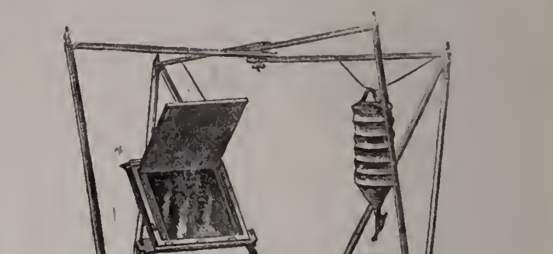
Apparatus.

SMART'S TENT.

As the season for landscape photography is rapidly advancing, we propose to describe from time to time the various tents, developing boxes, and other contrivances for working wet processes in the field; both those which are in the market and those of amateurs which appear to possess especial points of value. We shall be glad to receive from our readers and correspondents any hints on contrivances of their own of this kind, or of the results of their experience in the working of those already before the public.

As we have received repeated enquiries on the subject of Smart's tent, we shall commence by describing it. This is one of the largest and most convenient tents we have seen, ample space and ventilation being provided for working large plates without difficulty. It is in no sense a box, as some tents might perhaps be correctly designated; but a tent in which the covering comes down to the ground, and forms a rectangular apartment of six feet high, and three feet wide and deep.

The engraving below shows the interior with its equipment, prepared for operations.



As will be seen, the framework consists of a complete system of triangles, by which the greatest possible rigidity and strength is obtained with the slightest possible materials. The long rods which cross each other forming the supports, are each in two pieces, fitting into each other by means of springs and sockets. Every joint in the framework is readily matched to its fellow by means of an ingenious series of red and black marks, which by their arrangement prevent the chance of mistake. Three feet from the ground, just at the point of crossing, in the supports, is a table which folds up when the tent is packed, and when opened out gives a space for working on of three feet by one foot and a half. This space is encumbered with the least possible number of working appliances, as the bath is hooked on to the front edge of the table, and there is a neat contrivance for holding the dark-slide in one corner just above the table. This arrangement, for keeping the dark-slide off the table, is exceedingly convenient. One of the greatest difficulties of working plates larger than stereoscopic size in a dark tent, arises from the awkwardness of having to place a large slide, with the back open, upon a table already filled with bottles, bath, measures, and trays. As the dark-slide is placed here the plate is easily placed in it whilst in position: and on returning, to develop, it is replaced in its corner, the back lifted, and the plate received on to a pneumatic holder, without ever touching it with the fingers. At the opposite corner a collapsible water bottle is suspended with a spring tap, upon the pressure of which the water for washing the plate after development is readily made to cover the plate. A folding tray of india-rubber cloth, with fixed rigid sides, and moveable ends, which, on being put in their places distend it to proper shape, is provided for catching the waste solutions. The cover is quite impervious to light, except the nonactinic light passing through the window of yellow oiled silk. It is attached very conveniently to the frame-work, and held down at the bottom by means of eyes, into which the ends of the legs are placed. For use in windy weather a steadying line is attached to the top of the tent, which may be pinned to the ground on the windward side. The whole arrangement of the tent and its accessories is very ingenious and convenient.

When fixed in the field nothing appears wanting to its completeness as a dark-room. Its only drawbacks, in our estimation, are not drawbacks *per se;* but only so in relation to the wants of some photographers. The first is its weight; this is exceedingly trifling when compared with its extent and convenience, being, when packed up complete, only about twenty pounds. But to the photographer who is anxious to carry his traps for a day's work in his hand, this weight, together with camera, &c., would be quite out of the question to carry. The next drawback is one which really has no relation at all to the tent in itself, and we only refer to it because it is necessarily a point of importance to some of our young readers: we refer to the price. This, we have no doubt, is very moderate in relation to its value; but a cost of six guineas will necessarily limit its use to those to whom thorough efficiency is a more important consideration than the first cost of their apparatus. We have carefully examined the tent, and we are familiar with the pictures of Mr. Vernon Heath and others, the negatives of which, 12 in. by 10 in., have been produced in these tents; and, so far as we can judge without actual experiment, should think, that little more difficulty need be experienced in doing good work in the field, with such convenience than in the dark-room at home.

A CONVENIENT TOURIST'S CAMERA.

WE have just had made for us, by Mr. Meagher, a very neat and comprehensive portable camera for the field, which, as it possesses many points of utility and convenience, whilst, not perhaps new in themselves, we have not before met with in combination, we shall describe for the benefit of our readers.

It is intended for stereoscopic plates, and for plates of $7\frac{1}{2}$ inches by 5 inches, the outside measurement, when packed up, being about 9 inches by 8 inches, and 4 inches deep. It has a bellows body, expanding from a focus of $3\frac{1}{2}$ inches to $9\frac{1}{2}$ inches; thus allowing of the use of Dallmeyer's, Ross's, or similar stereoscopic lenses of short focus: or of the same lenses where only the front lens of the combination is used, having a focus of 6 inches. It also permits of the copying of objects and camera printing of transparencies the full size, by using the combination and extending the camera to 9 inches, which is double the equivalent focus. When stereoscopic pictures are not required, there is an extra front, to which is attached one of Dallmeyer's triple achromatic lenses of $7\frac{8}{10}$ inches focus, producing a negative of upwards of 6 inches by 5 inches.

When not in use for stereoscopic work the central partition is removed from the camera. The front may not only be raised, but also depressed, so as to allow of either more sky or more foreground, as the exigencies of the picture may require. The focussing screen is never removed from the camera, but hinged at the top, and turned back on the top of the camera; so that there is no danger of its being either broken, or laid down and forgotten. The dark frames carrying the plate enter at the side of the camera, and the slide pulling out horizontally, there is not the same danger of light striking in as when it is pulled out from the top. The focussing is effected from behind by means of the screw arrangement, the handle or winch is fixed instead of moveable, and folds up out of the way. The tail-board is hinged and folds up, thus protecting the ground-glass, and making the camera into a compact mahogany box of the size we have before mentioned. There was some difficulty effecting the union of the two advantages of a hinged tail-board and screw-focussing adjustment, which we were anxious to secure; but Mr. Meagher eventually managed it very cleverly. The tail-board is held rigidly in position both when folded up and when down, for use by side-pieces moving on a centre. Altogether the camera works well; it is rigid and firm; and none of the advantages are obtained at the expense of disadvantages. It is light and portable, and convenient to work; easily put into working trim, and easily packed up again, whilst, at scarcely any extra cost of weight or space, facilities for working plates 7 inches by 5 are obtained in a stereoscopic equipment, an arrangement adopted, we believe, by Mr. Wilson, of Aberdeen, in his stereoscopic camera.

We may here mention a convenient binocular camera for stereoscopic purposes only, which Mr. Meagher has recently brought under our notice. Unlike the ingenious binocular camera of Mr. Hare, which has two distinct bodies, this has merely one large bellows, the division between the two pictures in the bellows being managed by means of elastic material, which collapses or expands with the movement of the bellows. This camera, like the one we have described of our own, has a hinged-focussing screen, screw adjustment for focussing, hinged tail-board and other conveniences. It has also an ingenious swing-back arrangement, that part of the body receiving the dark-slide moving on a centre, which the flexible bellows readily allows it to do. The body expands from $3\frac{1}{2}$ inches to $7\frac{1}{2}$ for lenses of short and long foci. It is light, compact, portable, and complete.

Photographic Tourist.

PHOTOGRAPHIC RAMBLES IN WALES.—No. 2.*

BY J. H. JONES.

THE next morning, finding upon inquiries that there was nothing of very great attraction, until I should get to Ystalyfera, a distance of six miles, I thought I would take a walk while waiting for a conveyance, and so I started in search of a medicinal spring, discovered about three years ago, about which Madame Rumour had said a great deal, and which is now known far and near by the name of the Gellyowen Spa; the road to it is up a hill to the left of the Pontardawe road, which I ascended for about two miles; I did not take the camera with me, for which I was sorry, because many a beautiful view

* Continued from p. 213.

was to be had, some of them I should have liked very much. When I reached the summit of the hill I was rather surprised, for on loking around me, to see the whereabouts of a certain house, called the *Gellyonen Spa Hotel*, I could see nothing but a rough looking cottage, and an Unitarian chapel, *it could not be the latter, of course*, therefore, it must be the former; but not caring to be satisfied on the subject, I began searching for the spring, which after many a jump and leap—for the ground is nothing but a swamp—I discovered it lies in a trench, or gully, about four feet deep, about midway between the said cottage and chapel. The smell of the sulphur as I approached it was nearly suffocating, and for a time I could not pluck up courage to taste it, for I thought to myself, well, if the smell is so bad what must the taste be; but at last I summed up my resolution and tasted it, oh! it is not so bad as I imagined! I therefore, to follow out the proper prescription, which is, to "*drink half a pint and then run a mile*," I did so, and then, as fast as I could scamper, off I bolted towards the chapel.

As I entered the graveyard a feeling of awe took possession of me, for here I was alone with the dead, the solemn stillness reigning around added to this feeling; so after spending a few minutes in looking at and reading the inscriptions on the graves, I returned, and once more drank off the waters of the spring; this spring, in my opinion, gains its medicinal property from the surrounding swamp, for the ground is nothing but one mass of decayed vegetation; I tasted of several of the pools in the neighbourhood of the spring, all of which had a peculiar taste; these pools, having no visible outlet must, in my opinion, percolate through the ground, and find their way to the opening of the spring, which is a deep long gully much in shape like the drains in a meadow. I now made the best of my way back to the village, and got there just in time to meet the conveyance I expected.

Although there is nothing of very great interest, still the drive from here to Ystalyfera was very pleasant indeed; the road lying through a series of villages more or less pleasing, and the amusing tales told by the Jehu, a lively sort of fellow, served to pass the time away very pleasantly.

Alighting at Ystalyfera I looked around me, and soon found something to fire a plate at, in the shape of three bridges, a railway bridge, a canal bridge, and a large five-arched bridge crossing the river, through the arches of which the previous two could be seen.

Midway between here and Ystradgynlais, at which place I intended stopping, there are several very nice views to be had; one especially struck me as very beautiful, a small and very old bridge, which spans the canal near Ynyscedwyn House, the seat of Mr. Gough, and the turnpike road and canal running side by side, luxuriantly fringed with trees, through which a flood of golden light from the declining sun lit up a group of colliers who were filling the coal barges.

Finding by inquiries that the walk by the side of the canal was the shortest, I took it, and passed many a charming scene, until I arrived at the village of Ystradgynlais, which is most delightfully situated, I made my way to the Ynyscedwyn Arms, a favourite resort of the tourist, and also the commercial travellers who come to this vale on pleasure or business, a house where every accommodation can be had. As I spent six weeks in this village, exploring the beauties of the neighbourhood, perhaps it will not be amiss, therefore, if I subjoin a list of how this valley should be worked, for the benefit of those who might wish to visit it. First day, from Swansea to Pontardawe; second day, the local views as I have described them, in and near Pontardawe; third day, from Pontardawe to Ystradgynlais; fourth day, the local views to the east and south of the village, amongst which will be found the Ynyscedwyn Iron Works, the residence of the proprietor, a handsome structure called the *Plas*, also the church, and a splendid view of the valley—embracing many points of interest—from a hill on the Brecnockshire road; a few hours might also be spent very agreeably in the evening at the Iron Works; fifth day, a ramble to the north of the village, through Cwm Gaer and Tir-y-cwn, the last, a most delightful glen, the property of the Rev. Thomas Williams, a relative of the Williamses of Aberpergwm, in the Neath Valley—who is a gentleman of unbounded hospitality. This glen is deserving of especial attention, as it possesses many scenes of romantic and delightful grandeur, nature seems to have lavished its beauties here with no niggardly hand. The sixth day might be very pleasantly and usefully employed in following the course of the canal upward, until you arrive at the Brecnockshire road; as you approach the Black Mountain, from which the Tawe springs, a scene singularly beautiful appears before you; the wildness of the crags pointing and projecting in every conceivable form, is contrasted with the incipient foliage immediately below. The source of the river is very near the pathway over the mountain; the new-born stream rushes impetuously over pebbles and fragments of rock, until collecting itself into a basin, just above the fall, from which it makes a mighty leap of eighty feet to its bed below, forming a splendid fall, known by the name of Schood-yr-Henrydd. Three or four pictures of great beauty may be had here; the river then seems to derive fresh force from the steepness of its descent, rather than from the volume of water, which shapes its confined but everlasting course. The early progress of this river seemed to me much more pictueresque than that of the Usk, though little known and less celebrated; this vale, even in the upper part, has an aspect uncommon to such districts, in being studded with white cottages, this circumstance communicates a pleasing gaiety to the otherwise sequestered dell, overshadowed with mountains rising above mountains, in the rude and fantastical majesty of fashionless variety. The grand depository of lime which these mountains furnish for the use of the more populous and cultivated parts, with the facility of its conveyance down the neighbouring canal, sufficiently accounts for the sprinkling of inhabitants, who would not otherwise have sought so bewildered and inclement a spot. But the most romantic part, and greatest curiosity, of this extraordinary neighbourhood is the Cribbath Lime Rock; it rears itself perpendicularly to an immense height, with frequent projections of seemingly decumbent fragments. The abruptness of this, like most of the rocks, standing singly, unencumbered by lower hillocks at its base, occasion the scenery here to resemble greatly that of North Wales.

The river on reaching the level of the vale, assumes a beauty nearly equalling the most distinguished streams of this well-watered country. It is remarkably sinuous in its course, through meadows rich in verdure, and woods luxuriant in growth and foliage. In returning, the road is romantically overhung and confined between the noble woods on the slope and the river running at the bottom; many picturesque "tit-bits" may be had along this road. But the view from the half-demolished wooden bridge, up the river, with the loftier mountains terminating the distance, is uncommonly beautiful. If the night could be spent here it would be worth while, for this scene is particularly beautiful by moonlight, and would well repay the extra inconvenience attending the stay, for the soft and mellow colour, the interesting obscurity, by which objects derive an ideal importance from their indistinctness, the luminousness of the water, reflecting the silvery beams, all conspire to render a night scene in such a region most irresistibly fascinating.

I cannot conclude this paper without expressing a wish that the untamed beauty of these hallowed retreats, may long be preserved from the invasion of business, and the profanation of the engineer, unless the interests of agriculture or commerce were to be very extensively benefited by the introduction of busy human labour among the sports of nature; and also to express my gratitude for the many, very many tokens of kindness which I received from those friends into whose company I was thrown during my sojourn in the Swansea Valley.

Perhaps as an "Appendix" the following may prove interesting. A few days after my arrival at Ystradgynlais, whenever I went out with the camera, I was assailed on all sides by the inhabitants—men, women, and children—whom I should meet, who, after dropping a curtsey or scraping a bow, would say, "Drag my picture, Sir;" at first I could not understand what they meant by it; but when I was told that the word "drag" was intended for "draw," I had a hearty laugh. There was also a little boy, who, as regularly as the day would come, would be waiting for me, and directly he would see me, would say "*a lluniad*," and would follow me wherever I went, and, no matter how far, or how long I stayed, would be sure to return with me; whether this was done out of curiosity, or for the few coppers I gave him, I cannot tell, but very useful indeed was little Dan, and added a charm to many of my pictures by the natural childlike ways in which he would place himself for my convenience. I shall never forget the look of astonishment, wonder, and curiosity, which exhibited itself on his face, when I showed him a print of a negative, in which he sat on a stone near a waterfall; with his fat chubby hand he pointed to himself in the picture, and cried "Dan's lluniad," and then to the fall, and cried "*Gor Cwmpa*," and then off he went, and collected a lot of boys to come and look at it.

Correspondence.

PHOTOGRAPHY IN GERMANY.

Elberfeld, 17th May, 1861.

I REGRET to have to inform you of the death of one our most esteemed and skilful photographers, F. von Radl, Bart., of Augsburg, late member of the Council of the General Association of German Photographers, and chief of a large photographic institution. Some days before his death he sent to the *Photographisches Archiv* an article "On the Positive Paper Process," of which I will give you a short *resumé*.

Beyond the bad washing of positive prints there are yet a certain number of causes acting detrimentally upon the proofs. One of these causes is to be found in the card upon which the copies are mounted.

Every photographer has remarked the many particles of iron contained in these cards. The paper is bleached by chlorine, a great deal of which remains in the paper. The cards are drawn through iron rollers when yet humid, the moisture attacks the iron and thus chloride of iron and small particles of iron are deposited in the surface of the card-paper; they attack the print and destroy it after some time. The manufacturers of paper should employ hyposulphite of alum for bleaching, because this preparation does not cause the development of acid, as chloride of lime does.

The difference between several sorts of positive paper must be taken into consideration. A strong salted paper must remain longer and upon a stronger nitrate bath, than a slightly salted one, or when many sheets of paper are to be sensitized during one day, the strong salted should be prepared first, and afterwards the slightly salted ones. I once sensitized a very fine surfaced paper upon my usual 50-grain bath, and got very dull, bad prints with it; but having reduced the strength of the bath to 30 grains per ounce, and sensitized only three minutes, instead of six, I got very surprising results. The strength of my nitrate bath is tested by the known areometer.

For one ounce of water I take:—

(*a*) Liesegang's arrowroot paper	...	48°
(*b*) Slightly albumenized	... ...	60° to 65°
(*c*) Highly „	... ...	70° to 75°

The arrowroot paper remains four minutes upon the bath, the albumenized five to six minutes.

The strength of the bath expressed in weights is this:—

(*a*) 1 oz. nitrate of silver	to	10 oz.	of water
(*b*) 1 „	„	8 „	„
(*c*) 1 „	„	6 to 7	„

I add some drops of nitric acid to the bath for arrowroot paper. I find the addition of citric acid is very valuable. The tone of the print becomes exceedingly clear and goes over to the violet; also the paper does not discolour so rapidly, especially when a little nitric acid is added; in this case the use of preservative cases may be spared.

I have often found that too strong baths are of no use for paper prints. After sensitizing I pour the discoloured bath into the bottle and add some China clay. I do not like, as Mr. Fry proposed, to dissolve the nitrate of silver in common water, because it contains so many different compositions, that very often a bath may be entirely spoiled by it. Every photographer should examine the quality of the water he uses for washing the prints.

For large reproductions of cartoons, paintings, &c., Mr. Albert, of Munich, has now introduced the development printing. He prints every day some hundreds of various productions of the art and of the finest description.

The Photographic Society of Vienna has now held two *séances*. Mr. Martin has been appointed president of this new society. The proceediugs offer no features of much interest.

M. Angerer, the excellent Vienna photographer, showed some enlarged portraits produced from visiting card negatives by the solar camera. For the small album portraits large objectives of short focus are now generally preferred, some of our first photographers are using lenses of 4 inches diameter, which cover only 4½ inches; but I think this is not necessary. I inclose a card portrait made by Nadar with a half-plate lens, it is sharp enough everywhere.

A small "Catechism of Photography," by Dr. Schnauss, has been published at Leipsic.

Last week I visited the new Exhibition of the Paris Photographic Society. The most important are the fine enlarged landscapes and portraits of the Count Olympe Aguado. Everything is perfect in his prints, the shadows are transparent, the lights quite full of half tone, and the whole is of a very plastic effect. I saw the Count at work in his private gallery of the Place Vendôme. He uses the ordinary Woodward's solar camera, and plain salted paper, which is exposed wet aud upon wet filtering paper. He lays the nitrate solution on the paper with a glass triangle.

The enlarged prints by Delessert are not sharp enough, and possess too great contrasts. Evidently his negatives are not adapted for enlargement. Another first-rate enlarged portrait is exhibited by Messrs. Mayer and Pierson. Very interesting also are the stereoscopic views of Messrs. Ferrier, made with Dallmeyer's new stereoscopic apparatus; the pictures of the "Boulevard de Sebastopol" are surely taken instantaneously, every figure, carriage, &c., being perfectly sharp. The proofs have been made upon albumenized glass plates. Some days ago I made myself several instantaneous views of streets, and must confess this apparatus works excellently.

The best portraits and views exhibited by foreign photographers are those of Claudet, Maxwell Lyte, and Angerer. Another German artist, now living at Paris, Mr. Hanfstängl, has sent some excellent portraits.

The *carte de visite* portraits are exhibited in large numbers by Mayer, Ken, Pesme, and Pierre Petit.

Altogether more than 1,400 prints are exhibited by 150 photographers. PAUL E. LIESEGANG.

PHOTOGRAPHY IN THE TROPICS.

Rio de Janeiro, April 6, 1861.

DEAR SIR,—I have often seen in the PHOTOGRAPHIC NEWS letters from correspondents in respect to "toning difficulties." These have always astonished me, never having had any failures in my own practice. You may fancy then my astonishment when my last batch of prints turned out a complete failure. I have always followed the instructions given by "R." in No. 70 of the NEWS. I turn fifteen grains of chloride of gold into the auro-chloride, keeping the solution in a stock bottle, using as occasion offers in the proportion of one drachm to four ounces of filtered water (not distilled). About three weeks since I prepared a fresh solution of the auro-chloride, of which I used one drachm; the prints toning perfectly. A few days ago I printed twenty stereograms, and mixing the usual bath, I was greatly surprised to find it apparently inoperative; thinking I must have made some mistake, after fifteen minutes or so had elapsed, I well washed the prints, threw away the bath, washed dish and measures, and, mixing one drachm of the auro-chloride solution with four ounces of water, replaced many of the prints. Those that had been the least over-printed, I kept back. Most of these are of an even brown tone, such as I have generally obtained by only a very slight immersion in the toning bath; others very unequal—brown in places—purple in other parts. As an example, I send No. 1. The new bath had no more effect than the previous one. I left the prints in it for *two hours*, and then washed and fixed No. 2, with the intention of asking your opinion. The bath seemed to have no *bleaching* effect at all; indeed, this print appears more over-printed than it did when removed from the printing-frame. Half the prints were taken on the paper I had previously been working with, the other half on a new supply received from Messrs. Horne and Thornthwaite. But as I could detect no difference in the prints the change of paper can have had nothing to do with my failure. I have always been able to get either brown or black tones according to the extent to which the stereograms were over-printed. I send you two (Nos. 3 and 4) of the previous batch, when everything went well. They are the only ones I have left on hand, and they are far from being the best then produced.

If one of your correspondents who has been accustomed to photographing in hot climates would kindly give a few hints as to the best process and modes of manipulation, he would confer a great boon on many subscribers who, like myself, have but little time to devote to photography, and who have to blunder through innumerable failures on the road to success. Developing solutions, time of exposure, have all to be altered from what we have usually been accustomed to. The exposure is considerably longer than in England: for example, No. 4, taken in full sunshine, about 11 o'clock, a.m., with wet collodion, and Powell's Registered Stereoscopic Camera, and 4¼ inch focus lens, was exposed for 35 seconds, and this was certainly not too much. A snowy appearance is a very common defect in sunlit views in this country, in this case the white in the foreground is *sand*.

In many parts the roads have no hard surface, but are nothing more than bands of loose, glistening sand, with irregular patches of herbage springing up here and there at the sides, where the traffic does not interfere with its growth. No. 3 was taken with the same camera but on one of ———'s dry plates, exposure 5 minutes. Out of some dozens of these plates I have only succeeded in getting half-a-dozen passable negatives on account of blisters in the development which print as white spots. You will detect the presence of these spots on the distant mountains near the sky line.

After trying a tent for out-door photography, which was an entire failure, the heat being so excessive, I attempted to prepare dry plates of my own. I tried the collodio-albumen, but never could produce a plate free from stains when developed. They invariably reddened all over soon after the developer was applied. I afterwards prepared six Fothergill plates, with which I obtained one negative as fine as any I have, the others were failures only through under-exposure; they developed cleanly and not a stain could be detected on any of them even after prolonged development. I was now convinced I had hit upon the safe and easy process. I thereupon prepared a dozen plates with the intention of exposing the following morning (as on the previous occasion) a sudden change of weather came on and I was unable to do anything for a fortnight. I then took a turn amongst the hills; but on my return no sooner did I apply the developer than they immediately became stained. I next tried the albumen, only preparing four plates, the result was so unsatisfactory that I gave the process up as too difficult. The details came out very fine; but in each case the glass was more sensitive in one part than the other, through, I suppose, the albumen not having been properly applied so as to form an even coating. In despair I took to wet collodion again, and turned my tent into a developing chamber, by attaching in front two sleeves for my arms to pass through, and a small piece of yellow glass for seeing through; the view No. 4 was taken on the first occasion I experimented with it. It is rather awkward to work after this fashion, but it answers, and I suppose will become less awkward each time I use it. Still, for all that, a certain dry process would be a great desideratum, because with half-a-dozen extra slides then it is possible to go to many points for interesting stereograms where a tent is difficult to set up.

I hope you will excuse my rambling details by considering that as I am not within the boundaries of the penny post I am not bound to have my say out in as few words as possible.

How is it possible to produce a portrait of an individual with *light blue eyes?* Is there any dodge in printing from the negative, to bring the eyes out more decidedly?

What is the yellow varnish used for glazing over portions of a negative that print too deeply? and how is it applied?

Having only a day occasionally at my disposal, and having had but a very slight practical insight into photographic manipulation in England, I can't expect to produce anything very superior; but if a few stereograms, from time to time, of subjects such as Nos. 3 and 4, would be of ANY interest to you, I shall have much pleasure in remitting them.

With many apologies for taxing your patience with such a confused statement of my grievances. I am, dear sir, yours respectfully, William H. Cock, C.E.

[Your toning difficulty has probably arisen from adding excess of carbonate of soda to the chloride of gold. The solution thus formed will tone perfectly well at first, but on being kept, gradually loses its toning properties from the entire change of the chloride into an oxide of gold, which has no toning properties in the absence of any chloride of gold to commence the toning action. This is the theory of Mr. Hardwich. The best plan is to keep the chloride of gold in a solution of definite strength, and add the alkali at the time of using it. The plan is simple and avoids all risk. We strongly suspect that much of the difficulty experienced in working the collodion process in tropical climates, arises rather from the decomposition of the collodion than from diminished actinism. We should like our correspondent to try the effect of a bromo-iodized collodion, and iron development, and let us know the result. Regarding the dry plates referred to, we have ourselves worked them and never met with the difficulties to which our correspondent refers. The difficulties you meet with in the collodio-albumen and Fothergill processes appear to arise from insufficient washing; the stains seem to indicate the presence of free silver. You must bear in mind that no process, however perfect in itself, can be certain in result unless the manipulations are certainly perfect. The only method of successfully dealing with light blue eyes in a portrait, is to preserve them from excess of light, always take care to have them more or less in shadow, and looking at something in shadow. The use of any transparent yellow pigment ground in varnish would give a yellow varnish. Gamboge is a natural yellow varnish soluble either in water or alcohol. We have not ourselves "doctored" negatives in that manner, but it could be applied with a camel-hair pencil. The use of a little yellow powder-colour is sometimes useful in giving points of vigour to a negative. These things should always be regarded as final resources, not as constant and necessary aids. The views are decidedly interesting, and we shall have pleasure in receiving them and hearing of your further success.—Ed.]

PHOTOGRAPHY AND INTOLERANCE.

SIR,—In common, no doubt, with all your readers I rejoice at the stand made by the Chief Baron against the proposal to class our productions amongst mechanical appliances in the coming International Exhibition. It will be equally pleasant if a similar stand is made against the interference of certain individuals in the matter of portraits and artistic additions to landscapes, as the following fact will shew.

A friend of mine, when lately preparing to take a view of a church in B——shire, requested a girl of the village to place herself so as to be included in his picture; but no sooner had she done so, than the Clergyman issued from his Parsonage and drove her away in great wrath. He then, addressing my friend, said, "I would not have that girl in your picture for a hundred pounds!" To the very natural enquiry "Why so, sir?" he received the uncourteous answer, "Oh! she is a little nasty Dissenter." My friend might have with truth rejoined that he also was a Dissenter, though neither "little" nor "nasty;" but, jesting apart, this is a species of intolerance which deserves not only publicity but censure. Are church people alone to be included in our pictures? If so, we may be likely ere long to see a West-end portrait gallery with a notice "No Dissenters admitted," the exclusion extending even to Weslyans, as to this denomination the girl, it appears, belonged. I inclose my card, although an occasional correspondent and constant reader. Yours, ALIQUIS.

[We had hoped that photography was one of those catholic arts and sciences that made "the whole world kin." We should think this is a very solitary case.—ED.]

THE SOCIETY AND THE EXHIBITION OF 1862.

SIR,—Does it not strike you that a society which has done so little for photography as a fine art has scarcely the right to step forward with so much indignation, and protest so loudly when other bodies treat it with the same feeling as it has uniformly displayed towards the new art itself?

What has this London Photographic Society done to foster the artistic capabilities of photography, that it should complain of its productions being classed with its apparatus, and its processes?

We sadly want a society devoted to photography as an art as well as a science, and nothing has more clearly demonstrated this to my mind than the treatment it seems likely to receive at the hands of those who manage affairs for next year's Great Exhibition. I am, dear sir,

ONE WHO BETTER LOVES SMALL DEEDS THAN LARGE WORDS.

[We can scarcely regard the past shortcomings of the society as any barrier to its present activity in a right direction. We are so glad to see it alive to the interests of the art and its votaries, that we are almost willing to regard one virtuous action as condoning all past faults.—ED.]

Photographic Notes and Queries.

BACKGROUNDS.

SIR,—I write to inform you, for the benefit of those amateurs who may be in want of a background, that if they follow the directions given by Mr. Gulliver in a recent number of the NEWS, they will have no cause to regret the experiment.

I have made a most excellent background by the means described, which I have attached to a roller, and (for the sake of convenience) treated exactly as though it were a bliud; the cloth will, however, fold without cracking, as stated by Mr. Gulliver.—Yours truly, FRED. YOUNG.

Blackheath Road, May 20, 1861.

STAINS AND STREAKS.

SIR,—I have just read the NEWS, one result of which occupation has been a most inordinate and uncontrollable fit of cachinnation. I beg pardon, not for one moment do I insinuate ought approaching to disrespect to the author of the paper on "How to Prevent Stains and Streaks in the Collodion Negatives," but to be told in a most serious and positive manner that too much light in the dark-room is the main, if not the sole cause of the above blemishes, is rather too much for an individual like myself, whose nervous system is very easily and speedily affected. I most unhesitatingly add my humble testimony to the value of your own remarks on this paper, and in addition thereto would venture to ask our friend if the constitution of the iodising compound, or a collodion giving a thick or thin film (opaque or translucent) has anything to do with the subject in question? As regards myself, using *clean* plates, *I cannot get a streaky or stained one.* I work Mr. Thomas's collodion in a Horne and Thornthwaite's dark-tent, which latter, owing to a fair amount of wear and tear, and a rather "sloppy" manipulator, has become a little warped, and actinic light streams in (I was going to say) in all directions, a crack here, one there, and pin-holes in the calico innumerable, yet I will "set up" in the sun, and get a perfect picture without trouble. Now for two examples, and I conclude, stating firstly that if any one doubt I shall be happy to show the negatives. In the bottom of my tent is a hole to pass out the water, and which, when manipulating, is covered over with a penny piece, being handy; last winter, while developing a view of Rainham Church, Essex, I discovered, to my dismay, the hole was not stopped (and right under the plate) of course I thought the picture spoiled, nevertheless, it dried all that could be wished. Again, a few days since, I was photographing a gentleman's mansion, and the only available dark-room for large plates was the coach-house next the stable, developing by the feeble and deceptive light of a candle. I imagined the plate literally burnt to pieces, house and sky one mass, so prepared another and reared the picture (developer still on) against the wall. I thought, however, that a glance by daylight at the result would be advisable as a guide to density; to my surprise, the plate was perfect; I therefore washed, redeveloped up with pyro and silver, and very successfully concluded my morning's work. I state these facts more to prove that actinic light will not always stain and streak the plate so much as the reasons aforesaid, than to boast of any "dodge" in manipulation, and inclosing my card, remain sir, respectfully yours, PHOS.

COLOUR IN SPIRIT VARNISH.

SIR,—Can you or any of you readers inform me how to decolourise spirit varnish for collodion negatives?—Yours, ZENO.

[We believe there are no efficient means of decolourising spirit varnish. All gums have the tendency to acquire colour, and if applied in a colourless state would acquire colour on the negative. The very thin film, however, will scarcely exercise a detrimental influence in an appreciable degree.—ED.]

ON MOUNTING PRINTS.

SIR,—The mounting of prints being to me a troublesome and unpleasant process, I was induced to try the mixture given at p. 211 of your present volume, but unfortunately without enjoying the advantages promised by the writer of that article; on the contrary, I find that with his preparation the prints still "cockle," that wherever the mixture happens to touch the face of the print (an accident of frequent occurrence with unpractised hands), there the albumen surface is destroyed and the print seriously damaged; moreover, on opening the bottle today (a fortnight after mixing), I find the surface of the contents thickly covered with blue mould.

After trying various plans, my advice to brother amateurs, who have only to mount a few prints now and then, is, stick to fresh-mixed starch paste; there does not appear to be anything else so easily managed or so trustworthy. A good method of preparing starch paste was given some time back in the *Amateur Mechanic* series of papers. By the way, it seems to me that a practical article or two on the subject of attaching the print properly to its cardboard support, might be made really useful. The difficulty with stereo prints is but slight, the vexations increase with the size of the picture. "How to clean a plate" has long been a standing topic with societies in want of a subject; why not vary it a little by going to the opposite end of the matter, and teach us "how to mount a print?"—Yours very truly, D.

[We think our correspondent may in some respect have made a slight error in the preparation, as the method to which he refers was from a correspondent whose suggestions are always eminently practical and successful. Starch paste is, however, always safe and simple. We shall bear in mind the suggestion on the subject of mounting.—ED.]

Talk in the Studio.

Dr. Hill Norris's Extra Sensitive Dry Plates.—We exposed a couple of Dr. Hill Norris's extra quick dry plates a few days ago, which we had had about six months in our possession. They were in no way deteriorated from this length of keeping. They were both over-exposed with five seconds exposure. The sunlight was bright, and a stereo lens was used with half-inch stop. The only difference observed as the result of keeping was a considerable accession of redness in the negative, which is of a rich ruby tint.

Photographic Society of Scotland.—The annual meeting of this society was held on the 14th. The report shows the society to be in a prosperous state, a balance of upwards of £386 being in the hands of the treasurer. We shall give the report of the council next week.

North London Photographic Association.—The last meeting, before the summer recess, was held on Wednesday evening. A camera arranged with an especial view to the copying of engravings, was described by Mr. Barnard, and a paper on mounting stereographs was read by Mr. Shadbolt. A detailed report will appear in our next.

Photography on Wood.—The *London Review* has an interesting article on this subject, which does not, however, explain any process. A specimen engraving by Mr. Thomas Bolton is given, which is very effective. The subject is "Christ as the good Shepherd," being a copy of a stained-glass window recently erected in Abington Church, Northampton.

Photographic Enamelling.—M. Joubert recently read a paper on his method of producing photographic pictures in enamel colours on glass, at the Society of Arts.

Instantaneous Photographs.—We have received some specimens of a beautiful series of instantaneous photographs of Paris, just issued by the London Stereoscopic Company, executed by their talented artist, Mr. W. England. They, for the most part, represent scenes in the crowded streets of the French capital in the midst of its busy traffic. In many of them the conditions of complete instantaneity are perfectly fulfilled, for we have walking figures with foot uplifted beautifully rendered, and rapidly driven equipages produced without blurring. In addition to their interest as instantaneous pictures of scenes so full of subject as Parisian streets, they are harmonious photographs without the common enormity of white skies. There is in all cases a tone over the skies, and in some the natural clouds. The only point at all at fault, is the lens, which has not always given perfect sharpness and illumination to the edges, the results, we presume, of the large aperture necessary to instantaneous pictures.

To Correspondents.

T. K.—We have had no experience with Bland and Long's dry plates; but it is not improbable that after keeping for upwards of two years they may have become useless. Perhaps a direct application to that firm may gain you some information. The gallic acid solution of the colour of port wine, which has been kept mixed for two years, is quite useless. Your old collodion may probably be utilized by adding a bromide to it. Try first the addition of half a grain to each ounce; and if that is not sufficient add a grain. Use iron development with it.

N. W.—Mr. Barber's instructions are very definite. He says, add liquor potassa until a permanent precipitate is formed. The smallest amount of oxide thrown down and not redissolved is a permanent precipitate. We should have thought the term could not possibly have been misunderstood. The amount of nitric acid which may be present in any commercial sample of nitrate of silver, is altogether indefinite, some samples are nearly neutral, whilst others contain much nitric acid; it would be impossible, therefore, to say what amount of oxide of silver, or of any alkali would be necessary to neutralize it. If a large amount of oxide of silver were required to neutralize it, a large quantity of nitric acid must have been present. The amount of alkalinity present in a bath which has been neutralized with oxide of silver and filtered is so slight, that an infinitesimal portion of nitric acid would neutralize it. Possibly you are not sufficiently careful in your experiments, or you do not allow sufficient time for all the reactions to take place, before you draw conclusions. The most lucid instructions will be useless unless you exercise care and judgment.

Plato.—The print you forward is an excellent tone for those who desire black tones. Personally, we prefer them a little warmer. We see no reason to doubt that it has been produced by means of alkaline gold toning as we have ourselves produced, and often seen others produce, equally rich black tones by that method. Good paper, a strong silver bath, and a vigorous negative, are all that are required. This print has been produced from a very vigorous negative. Black tones cannot be produced from a weak negative, without losing the whites. *Rive* paper will be most likely to give you warm black tones, if you tone deep enough. Saxe paper readily gives black tones, but there is a tendency to the slatey coldness.

J. B. R.—Your name shall be inserted. Regarding the blistering to which you refer, we can only suggest two causes, using a contractile instead of a powdery collodion, or coating the plate when it is not perfectly clean or dry. The collodion you are using ought to be the very best, being supplied by such a successful manipulator. The other to which you refer we have no practical knowledge of, but we see no reason to regard it as an improvement on what you already have. Perhaps the use of a bath containing nitric acid, for the first exciting, may aid blistering.

T. P. E.—We see no reason why, with ordinary care, you should not succeed in making good collodion. The formulæ given in the Photographic News Almanac may be relied upon, as we use it ourselves practically. If you intend to make collodion, by all means begin at the beginning and make your own pyroxyline; it is upon that your success will mainly depend. We doubt whether there is such a thing as thoroughly good pyroxyline in the market for sale. The price at which it is often quoted in catalogues would be wholly inadequate to pay for the manufacture of a reliable article. Begin at the beginning and follow instructions carefully expecting the possibility of your first attempt or two not being entirely successful; but persevere until you get satisfactory results.

T. G.—We are obliged by your contrivance for the dark room window, which we will make use of shortly. We will enquire about the negatives to which you refer.

J. T.—The addition of acetate of silver to the bath would give you greater intensity; but we should recommend you in preference to use another collodion. Do you intensify at all before fixing? because the collodion you name would probably not give you sufficient intensity for negatives with iron development only. Ponting's collodion is generally accompanied by directions for the condition of bath most suitable for it, and is generally best developed with pyrogallic acid. Your specimen is very respectable for a beginner. For such a subject you should use a smaller stop; this picture appears to have been taken with nearly full aperture.

M. D.—Kinnear's camera with the improvements of either of the makers you name is a very useful article, and would do very well for copying. It is difficult to say whether its extension for focus is greater than that of ordinary bellows cameras, inasmuch as there is no standard length which can be described as ordinary; you can have them made to extend any length. The extension of a 10in. by 18in. Kinnear which we have in use, made by the latter of the makers you name, is about 16 inches. 2. We have not used a Voightlander's orthoscopic lens.

E. C. L.—In taking negatives to be intensified by means of bichloride of mercury, you may use your ordinary positive bath, and your ordinary positive collodion, if it give you a slight degree of intensity; if it give a very thin image add a little negative collodion to it. Develop with iron 15 grains, and glacial acetic acid 15 minims, to an ounce of water. Fix with hyposulphite of soda. Intensify with a weak solution of bichloride of mercury, say 3 grains to an ounce of water. Turn it yellow by means of a weak solution of iodide of potassium, say 1 or 2 grains to an ounce of water; or brown by means of dilute ammonia, one or two drops of liq. amm. fort. to an ounce of water. Varnish before using. Take care to expose sufficiently, and to wash well between the application of each fresh solution. The focus of a view lens is ascertained, as you mention, by focussing for a distant object, and measuring the distance of the lens from the ground glass. The equivalent focus of a portrait lens lies at a point somewhere between the front and back lenses of the combination. We have repeatedly given the means of ascertaining it. See Photographic News Almanac, p. 76.

G. H. E.—To prevent your prints becoming a cold black, do not leave them so long in the toning solution. Use the Rive paper, it is less liable to coldness than Saxe paper. The use of a little citric acid in your silver bath will also give you redder tones. The use of borax won't help you.

Jimby.—The mottling in the prints you send is simply the result of bad paper: so far as we can judge, that is the only cause. Try a Rive paper.

Jupiter A.—The streaks on your plate are caused by the condition of the bath, not by the developer. The addition of a little nitric acid may correct it. If not, add a little oxide of silver and place the bath in the sun for a few hours; then filter, and add nitric acid a drop at a time until it works, trying a plate each time. It ought then to give you brilliant positives. The developer you are now using has too much nitric acid. Use one drop instead of two. The defects in your collodion appear to arise from over iodising, the addition of a little plain collodion might put it right, or you may try adding a drop or two of distilled water to each ounce of collodion. Regarding the use of bichloride of mercury, see answer to E. C. L. Let us know of your success with your bath.

A Subscriber at the Hague.—Mr. Dawson's admirable table for ascertaining the strength of nitrate of silver solutions would be quite clear to you if you were familiar with the principle of "specific gravity." The subject is too long for explanation here. You will find it explained at p. 248 of our third volume, or in almost any elementary work on natural philosophy. Distilled water at 60° is the standard, and the specific gravity bottle holding 1000 grains of distilled water, will, when filled with the solution to be estimated, just give the results according to the silver the table indicates.

H. W. Ball.—The specimens sent do not indicate that your bath, or anything else, is out of order. You simply require a little shorter exposure. There are two or three methods by which you may get deeper blacks in your glass positives, that is, less deposit of silver on them. First, the addition of a little more nitric acid to your bath; second, the use of an older collodion; third, the addition to your collodion of a little tincture of iodine. It is often impossible for us to write letters by return of post, however anxious we may be to relieve our readers from difficulties. You will see this before we should have time to write to you.

F. E. G.—We are not familiar with the instrument to which you refer; but have seen very good negatives taken with it. We have received the specimens, but have not time to look at them; we hope to do so shortly. The stereograph is very good. We cannot say whether it is good enough for the purpose you name. We do not think much of the scheme.

G. W. Hale.—Certainty is rather a question of manipulation than of process, although some processes require less care to produce good results. We shall give another albumen process shortly; that used by Ferrier. We should imagine good views of Constantinople would sell. It would be desirable to have both stereoscopic pictures and larger ones. We admire the tone of your transparencies very much. You did not state how it was produced.

T. S.—All the advertisements you enclose are simply traps to catch the foolish. We have already more than once exposed "Lindorff's discovery." It simply consists in "setting off" an engraving newly printed in printer's ink, on to a piece of clean paper.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 144.—*June* 7, 1861.

M. FERRIER'S ALBUMEN PROCESS.

A singular controversy has recently occurred relative to the albumen process of M. Ferrier, whose exquisite transparencies have long been the admiration of photographers. Some half dozen years ago Mr. Negretti read a paper to the Photographic Society, which was published in the Society's *Journal*, describing an albumen process which had been communicated to him by M. Ferrier. Our Liverpool contemporary having recently published an article entitled "The Albumen Process of M. Ferrier, as practised by Mr. Negretti," which it appears was a *résumé* of the paper read in 1855, M. Ferrier emphatically denies that the process is his, or that he ever communicated it to Mr. Negretti. This gentleman, in his reply, mentions time and place when M. Ferrier explained his process, and showed it in operation, and moreover states that he had subsequently mentioned to M. Ferrier the fact of having detailed particulars to the Photographic Society, and that until this exhumation M. Ferrier neither disavowed the process, nor complained of its publication. He adds that so long as all manner of absurdities were published as to his method of working, and photographers were thus thrown off scent, M. Ferrier chuckled and held his peace; that he is a man who has never opened his lips to give photographers at large a hint, but allowed them, so far as he was concerned, to flounder about, wide of the mark; and that it is only since his, Mr. Negretti's, successful practice of the process, that M. Ferrier is concerned to deny it.

Just at this juncture, when Mr. Negretti's emphatic re-assertion of M. Ferrier's paternity regarding the process, and his own good faith in the matter, appeared to have set the matter at rest, doubts are re-awakened by the comments of an authority universally respected by photographers. Mr. Hardwich, in the same journal, expresses grave doubts as to whether the process published by Mr. Negretti is actually the one by which he produces the transparencies he issues, and asks him, in all plainness, for a definite answer on the subject, stating his conviction that unless Mr. Negretti makes a clean breast of this "he will be answerable for all the disappointments of the thousand and one amateurs and professionals, who, on the strength of his published successes, will weary themselves in the vain attempt to rival their teacher."

We remember an American story of a backwoodsman, doubtless of Milesian origin, who coming up to a spot where some fighting was going forward, regarding the origin or merits of which, or of the parties engaged in it, he knew nothing, at once inquired, "Is this a free fight?" and without waiting for an answer plunged into the thick of the *mêlée*. Now we have no disposition to emulate the belligerent backwoodsman; but as the subject in dispute is an interesting one to photographers, and as we think we can throw a little light upon it by independent evidence, we shall say a few words about the matter.

To refer to the latter part of the question first. We do not know what ground Mr. Hardwich may have for doubting that the process published is that now used in Mr. Negretti's establishment; but we have the assurance of a gentleman with unquestionable means of knowing, that the process, published by Mr. Negretti in 1855, was the one used for years in his establishment, and we have seen the transparencies so produced, which have all the characteristics of those now issued. We think it important here to reiterate what we have often before endeavoured to enforce; that less at any time belongs to a process than to the individual working it. No one dreams of doubting that the master-pieces of men like Williams or Bedford are produced by the wet collodion process. And yet it is well known that the vilest libels on the art are constantly perpetrated by the same process. A good process and reliable formulæ are unquestionably of vital importance; but certainty and success can come with no process without a patient and persevering compliance with the common-sense conditions of success.

Before remarking on the identity of the process with that of M. Ferrier, we will first give a brief epitome of Mr. Negretti's statement of formulæ and manipulations, which are as follows :—

To the albumen of ten fresh eggs, add one per cent. of iodide of ammonium, dissolved in twenty per cent. of distilled water: now beat up the albumen for about a quarter of an hour, till the whole is converted into a froth, so thick and hard that pieces may be pulled up bodily with the fork when plunged into it. The basin should now be carefully covered in with a sheet of paper to prevent the access of dust, and put aside for six hours. After the froth has subsided, a thick crust is formed at the top: this serves as a filter for the substratum of albumen, which has to force its way through the crust when being decanted from the basin on to the plate.

The dark room should be carefully freed from dust some two or three hours before it is used, the floor being watered and swept, and all shelves and ledges well wiped with a damp sponge; for dust is the principal cause of blemishes in the albumen film, and, to prevent disturbing it as much as possible, it is advisable to take in all material required at one time, just before commencing operations. It is desirable that the room should be kept at a moderate temperature, though this is not essential.

The plate holder is a round tapering stick, about half an inch in diameter and nine inches long, having at one end a small cup, about an inch in diameter. Round the edge of the cup, which is about a quarter of an inch thick, some gutta-percha is melted.

To coat the plate warm the gutta-percha of the plate-holder in the flame of a spirit lamp, then press it on the centre of the back of the plate: in a few seconds it will have cooled sufficiently to adhere firmly to the glass, so that it may be turned and whirled in any direction. Now hold up the plate, and with a soft flat brush remove any dust that may have stuck to the plate. Pour the albumen from the basin on to the plate in the same manner as if coating with collodion, and, if necessary, assist the even flowing with a glass rod. Drain the albumen off, first at one corner then at the other; tilt the plate, so that the fluid may again pass over it; again tilt the plate, and when the albumen has reached halfway across it, impart a rotatory motion to the glass by means of the holder worked between the hands; continue this for seven or eight seconds, then place the hand close under the plate and force it off the gutta-percha. If any dust fall upon the plate during the operation, draw a fine camel-hair pencil between the lips, and pick off any spots with the point. Place the plate in the drying box, in each alternate groove of which a board slides freely, so as to separate each plate one from the other. The inside of the box must be well dusted before use, and the boards cleaned and thoroughly dried before a fire or in the sun, so as to render them absorbent, otherwise the film will not dry easily.

The bath for sensitizing is a dish with a perfectly flat bottom made of plate glass, about one-third longer than the plate employed. The solution is as follows:

Nitrate of silver	10 parts.
Acetic acid	10 ,,
Distilled water	100 ,,

This is poured into the dish till it stands about a quarter of an inch high. The bath is then raised at one end so as to keep the solution at the other. The plate is placed in the empty part, albumenized surface upward, when by a dexterous movement of the hand the dish is brought level, and the solution allowed to pass quickly and evenly over tho plate. The plate should now be raised and lowered several times by means of a flattened silver wire, bent at one end into a right angle: in about forty seconds the plate may be removed from the bath. The same care must bo taken, as in sensitizing a collodion plate, that the solution passes evenly over tho film, for wherever there is a stoppage there will be a sharp clear line.

The plate when removed presents a nice light bluo tint. It must immediately be thoroughly washed back and front with distilled or rain water. The water should bo allowed to flow over it till no greasy streaks are perceptible. The plate is now drained, and may be used moist, or, if intended for keeping, they should be thoroughly dried, and stored away in the dark. The sensitizing solution should be filtered back into the stock bottle, and may be used over and over again, even when quite black.

The development is effected by a saturated solution of gallic acid, which has been warmed to a temperature of 80° Fahr., spread it rapidly over the plate with the aid of a soft brush, the hair being about an inch long. There is no fear of using tho brush freely, as it would almost require a knife to scratch the hardened albumen. After the solution has been on a minute or two pour off a portion, and to that remaining on the plate add some of the following:—

Nitrato of silver	2 parts.
Distilled water	100 ,,

Rest the brush on the plate, pour the nitrate solution over the brush, and rapidly mix the two solutions together. In a few seconds the picture begins to appear, if the plate has been properly exposed: if, however, it is under-exposed, the image does not appear until the solutions have been changed and the previous operation repeated several times.

Fix with hyposulphite of soda, and well wash.

The same formulæ are, we understand, used both for negatives and printing transparencies; the only difference made in the latter case being that as thin a film of albumen as possible is obtained, whilst for negatives a good body is desirable.

Mr. Sutton, in a recent number of the *Notes*, gives a statement of M. Ferrier's process as communicated by "one of the Council of the Photographic Society." We may state that the gentleman here referred to is Mr. T. R. Williams, of Regent Street, to whom the process was communicated by M. Ferrier, and by whom it was witnessed as worked by that gentleman. The name of Mr. Williams, which we have authority for using, will vouch for the technical accuracy as well as the veracity of the statement. We give below the process as stated in the *Notes*, with one or two comments suggested by the remarks of Mr. Williams thereon. It will be seen that although there are some differences in the formulæ, they are only such as might belong to the manipulations of one man at different periods. The process as stated below was used by M. Ferrier ten years ago:—

"There are probably few of our readers who have not been delighted with M. Ferrier's charming transparent slides, and who are not anxious to know how he takes his negatives, and prints from them. On the former point we are able to give accurate information, having been informed of the whole particulars of M. Ferrier's negative process by a distinguished photographer, one of the Council of the Photographic Society, who has actually worked with M. Ferrier, and witnessed the manipulation from beginning to end. The following aro the particulars with which we have been favoured, and they may be relied on for absolute accuracy, our information having been obtained from the very highest source. These particulars are now published for the first time, and have hitherto been kept a profound secret. Mr. Negretti has lately described an *imaginary** Ferrier process, which will be found in a recent number of this journal, and which is wrong in some important particulars.

"The following is M. Ferrier's negative process:—

"'A plate of glass of the stereoscopic size is first cleaned, and then stuck upon a holder having a long handle. It is first held horizantally, and iodized albumen is poured over it. It is then held in a vertical position, with the stick between tho hands, and made to revolve *slowly*, always in the same direction, so as to drive off the excess of albumen. The iodized albumen is made thus:—Ten grains of iodide of potassium are dissolved in a few drops of water, and the solution added to tho white of one egg. The whole is then beaten up, allowed to settle, and strained in the usual way.'"

There is a slight inaccuracy here we imagine. Mr. Williams called our attention to the fact that M. Ferrier did not strain or filter his solution, except so far as that operation was effected each time by the albumen flowing through the hard crusted froth on to the plate and back again into the vessel.

"The albumenized plate is next dried in a drying box, in the following way:—The box is made with grooves like a common plate box, into which the plates are put, but so far apart as to allow of tho insertion, between every pair, of a thin piece of hot baked porous wood, which absorbs the steam and dries them in a few hours. M. Ferrier uses no wonderful precautious to avoid dust upon the plate. He does not strip himself half naked, and plaster down his hair and beard with grease, as some wondermongers have affirmed. Ho simply holds between his teeth a pointed bit of wood about the size of a lucifer match, and when he holds the plato up before coating it he removes with the point of this bit of wood any particle of dust which may have fallen upon the plate. This first operation of albumenizing and drying is conducted in the bedroom of the inn where he happens to be staying."

Mr. Williams remarks that in this respect M. Ferrier, and M. Martin, with whose name photographers were much more familiar at the period referred to than at present, were strikingly opposite to each other in practice. M. Martin was as scrupulously careful to avoid dust as M. Ferrier was indifferent about it. Their respective results were, however, strikingly different. M. Martin's pictures were the finest of their day, and quite free from spots or defects, whilst those of M. Ferrier, although possessing much beauty, were frequently marred by the effects of this carelessness.

"To excite the dried albumenized plate, it is immersed in a bath of aceto-nitrate, which long use has rendered as black as ink. It is then washed in distilled water, and dried.

"The views are not taken in a binocular camera, but with only one lens, and one after the other, from stations wide apart. The right picture is taken upon the left end of tho plate, and *vice versâ*, so that there is no need to cut the negative in order that the prints may come right in the stereoscope.

"The development is effected by a saturated solution of gallic acid, with a littlo nitrate of silver added. The gallic acid is filtered into a small silver cup, and heated to about 180° over a spirit lamp. A few drops of aceto-nitrate are then added, and it is immediately poured over the plate, which has been previously wetted in a dish of water. This hot developer brings out the image very quickly, and after a time, the plate becomes stained. The developer is then poured off, and the stains cleaned away, by rubbing the film with a tuft of cotton wool. After this apparently rough treatment, which does no harm to the film, some fresh developer is heated and poured on again as before; and this is repeated until all the details are brought out, and proper intensity obtained. The picture is then fixed with hypo, and washed in the usual way. No varnish is required. The prints are taken by contact."

These details refer entirely to the negative process. Of M. Ferrier's method of producing transparencies, we have no information beyond that given by Mr. Negretti.

One of the chief points of difference between this formula and that given by Mr. Negretti consists in the amount, and the base of the iodide. In the latter, the iodide of ammonia is used, and barely five grains per ounce, whilst in the formula furnished to Mr. Williams, ten grains per ounce of iodide of potassium are used. It is, we believe, generally found amongst albumen experiments that considerable latitude may be used in regard to the amount of the iodide. It is just possible that the proportions stated by Mr. Negretti may be more suitable for the production of transparencies, whilst that given to Mr. Williams may be best for negatives.

* We think our friend, Mr. Sutton, has slightly overlooked the possible difference of time at which these processes may have been communicated by M. Ferrier, and their similarity in the main.—Ed. Photographic News.

It is generally admitted that the strength of the silver-bath and other things being equal, a large proportion of iodide gives greater sensitiveness to plates for negatives.

The same idea, in relation to the next essential point of difference, is apparent; we refer to the temperature of the developing solution. If our conjecture be correct, that the process given to Mr. Negretti had more especial reference to transparencies, and that given to Mr. Williams to negatives, be correct, the higher temperature of the developing solution would be readily accounted for; as we believe the great secret in a rapid albumen process is the use of a *very hot solution* for developing. We know this to be the practice of some of the successful manipulators in albumen, and the idea is borne out in the recently published pamphlet of M. Chevalier, in which a modification of the Taupenot process is stated to be as sensitive as wet collodion, and in it a hot solution of pyrogallic acid is used for developing. Mr. Cramb of Glasgow is stated to be in the habit of working a very rapid albumen process, an account of which was read to the Photographic Society of Scotland in the beginning of April. We are not in possession of it as yet, as it is publishing in small instalments. So far as the details are issued, we do not find any peculiarity which accounts for the rapidity of which we have heard, except the use of a bromide, as well as an iodide, an addition which is now generally used. As yet nothing about Mr. Cramb's development has been published; but we anticipate that the use of a hot developing solution will play an important part in the process. At the first blush of the thing it would naturally appear that a hot developer would only shorten the time of development and not of exposure; but a very little reflection will suggest that an energetic developer may materially shorten the exposure as well. To illustrate, we know that less exposure is required with iron development than with pyrogallic acid, simply in virtue of the former being a more energetic developer. It is probable that in all cases the action of light is instantaneous, if we had but a developer of sufficient energy to bring out the instantaneous impression.

It appears that Mr. Negretti does not regard the process given by him as suitable for a hot climate; and yet Signor Beato, whose name is well known in connection with Indian and Chinese photography, used nothing but albumen, and his landscapes are regarded by many as unsurpassed by anything yet published of Indian scenery. A formula supplied by him to one of our correspondents in India is as follows:

Albumen, whites of	20 eggs.
Iodide of potassium	154 grs.
Glacial acetic acid	40 drops.
Iodine	20 grs.

The plate, after being coated, and dried was to be excited when required in a bath of aceto-nitrate of silver, the strength of which is not stated. Before being excited the plate was to be steamed to soften the film. The plate was then thoroughly washed, dried, exposed, and developed with gallic acid. In India Signor Beato took portraits with an exposure of thirty seconds.

We are sorry to be compelled to add that mystification, and sometimes something worse, appears to be a characteristic clinging to many successful albumen operators. Signor Beato sold his formula to many amateur photographers in India: on comparing notes they were all found to be different, and few of them proved successful. The one we have given was, in the hands of our correspondent, the nearest to success, and from his account we glean that he only failed in manipulation, as he found difficulty in obtaining an even film or layer of albumen.

We shall shortly advert to the methods of other successful albumen manipulators.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

Very few fluorides are at present employed in photography; but as it is more than probable that these bodies may ultimately play a very important part in the future of our art, especially in the fixation of colour, a short account of the fluorides which are either in present use or of probable value will now follow. As the general characters of these salts are but little known we will first give a general outline of their properties. They, for the most part, resemble the chlorides, have no metallic lustre, and are easily fusible, but are not decomposed on ignition, either alone or with charcoal. The most characteristic property is their liberation of hydrofluoric acid upon mixing with oil of vitriol. The evolved hydrofluoric acid has the remarkable property of attacking and corroding glass. Some fluorides, as for instance those of tin and silver dissolve readily in water; others, such as those of potassium, sodium, and iron, are more sparingly soluble; some, as the fluorides of cadmium and strontium, are very slightly soluble, whilst a great many, as for instance those of barium, calcium, magnesium, &c., are insoluble.

Fluoride of Potassium is prepared by mixing (in a silver or platinum vessel) a solution of hydrofluoric acid with carbonate of potassa, in such quantity that the acid slightly predominates. The liquid is then to be evaporated, and the residue heated strongly to expel the excess of acid. The salt crystallizes in cubes similar to those of common salt. It fuses below a red-heat; has a sharp saline taste, and alkaline reaction, and is very deliquescent. Oil of vitriol, nitric or hydrochloric acids decompose it with evolution of corrosive vapours of hydrofluoric acid. Its solution in water even gradually causes the bottles in which it is kept to become dim. The crystals are insoluble in alcohol.

Fluoride of Sodium is formed in a similar way to the potassium salt, it crystallizes in cubes and octohedra, which are sometimes clear and sometimes opalescent, and often have a pearly lustre. The crystals decrepitate in the fire and fuse at a temperature just above the melting point of glass. Their taste is not so sharp as that of fluoride of potassium. They dissolve sparingly in water; 23 parts of water at the ordinary temperature dissolving at most only one part of fluoride of sodium, and no more even when heated. Alcohol takes up very little.

Fluoride of Calcium deserves mention, as it is the great source of all compounds of fluorine. It is found in the mineral kingdom as fluor spar, in which form it occurs in cubical crystals of various colours, white, blue, green or amethystine. Fluor spar is not easily decomposed except by sulphuric acid, which converts it into sulphate of lime with liberation of hydrofluoric acid. This property is constantly made use of in the arts for the purpose of etching and corroding glass. Some of the finest dimmed glass for focussing purposes may be made by exposing a sheet of polished glass on one side over a leaden tray, the bottom of which is covered with a mixture of coarsely powdered fluor spar and oil of vitriol to a pasty consistency. In a short time the glass will be found to be perfectly etched over its surface, and if a figure or design had been drawn upon it previously with wax (which is not attacked by hydrofluoric acid) the pattern would have been found permanently impressed upon the glass.

Fluoride of Silver.—This salt, from its properties, promises to become a very important salt to photographers, and well deserves full investigation. It is formed by dissolving oxide or carbonate of silver in an aqueous solution of hydrofluoric acid and evaporating to dryness. The salt is extremely soluble in water and deliquesces in the air. Its aqueous solution has a strongly metallic taste, blackens the skin, and is precipitated by all salts which ordinarily precipitate silver. When evaporated to dryness and heated, it fuses like the chloride of silver, and on cooling forms a greyish-black shining mass, having a lamino-radiated fracture. It is decomposed by long ignition in the air. By repeatedly evaporating and redissolving the aqueous solution of fluoride of silver, Unverdorben obtained a substance which was no longer soluble in water, but settled down in small soft laminæ: whilst moist it exhibited a golden colour, and metallic lustre; but after drying became yellow and glistening; by pressure it again acquired the colour and lustre of gold.

The solubility of this salt in water seems to point out the advisability of experiments being made with it as an addition to, or substitute for the nitrate bath. Whilst the fact of one of the products of its decomposition by light being hydrofluoric acid might be readily rendered available for a photographic process of etching on glass. Mr. R. Hunt has worked a little upon the photographic properties of fluoride of silver; but his experiments were evidently conducted under the supposition that fluoride of silver was an insoluble compound analogous to the chloride, bromide, or iodide, as in all cases he describes it as being produced by a process of double decomposition between nitrate of silver and a soluble fluoride.

The silver salt being, on the contrary, very soluble in water it is evident that no good results could be obtained by this mode of preparing it, as if it were even formed most of it would be washed out of the paper immediately. The following observations of Mr. Hunt are nevertheless, in default of more accurate knowledge on the subject, worthy of notice. He states* that paper washed over with fluoride of sodium, and then with nitrate of silver, is not more sensitive to light than the nitrate itself, but it eventually becomes darker. This is readily understood, when we consider that the easy solubility of fluoride of silver in water would cause it to dissolve in the nitrate of silver bath as soon as formed. This same compound was also submitted to prismatic analysis by Mr. Hunt. A paper was first washed with nitrate of silver, and then with fluoride of sodium. Under the spectrum the action commenced at the centre of the yellow ray, and rapidly proceeded upwards, arriving at its maximum in the blue ray. To the end of the indigo the action was very uniform; it then appeared to be very suddenly checked, and a brown tint was produced under the violet rays, all action ceasing a few lines beyond the luminous spectrum. Some faint indications of change were evident to the lowest edge of the yellow ray, but none whatever below that point. The colours of this spectrum are not a little remarkable. When the paper is slightly browned by diffused light previously to its being exposed to the action of the spectrum, the following order of colours soon becomes evident; a yellow line distinctly marks the space occupied by the yellow ray, and a green band the space of the green; through the blue and indigo region the colour is an intense blue, and over the violet a ruddy brown; these colours, says Mr. Hunt, are tolerably permanent. The same investigator has also proposed the employment of fluoride of silver in another manner in a photographic process, to which the name of *fluorotype* has been given. This process consists in the formation of a salt of silver, which Mr. Hunt supposes must be considered as the fluo-bromide of silver. A sheet of paper is to be first washed over with bromide of potassium, and then with fluoride of sodium; or the two salts may be united. The strength of the solutions should be as follows:—

Bromide of potassium	... 20 grains,
Distilled water ...	... 1 fluid ounce.
Fluoride of sodium ...	... 5 grains,
Distilled water ...	... 1 fluid ounce.

Mix a small quantity of these solutions together when the papers are to be prepared, and wash the paper once over with the mixture, and when dry apply nitrate of silver in solution, 60 grains to the ounce. These papers appear to keep for some weeks without injury, and they become impressed with good images in half a minute in the camera. This impression is not sufficiently strong to serve, in the state in which it is taken from the camera, for printing positives, but it may be rendered so by a subsequent process of development. The photograph is first soaked in water for a few minutes. It is then placed on a slab of porcelain, and a weak solution of protosulphate of iron poured over, which very readily darkens all the parts on which the light has acted to a deep brown; every object being brought out with great sharpness. When the best effect is produced the process must be stopped and the picture fixed with hyposulphite of soda.

* "Researches on Light," second edition, p. 123.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Finish.—A good photograph, perfect in gradation and detail, may be said to be highly finished; a bad one, wanting half-tone, and a proper degree of unity between the high lights, shadows, and reflected lights, is certainly unfinished.

Flexible.—In the pose of a figure, curved and bending lines, by conveying an impression of flexibility, define qualities the reverse of those which assume an appearance of immovability and stiffness. To such a pose this term would be applied.

Force.—Obtained generally by a judicious use of contrast, but frequently to be secured by the skilful disposition and arrangement of a picture's various parts. Used to describe effects in opposition to those which are defined as tame, feeble, or wanting in effect.

Foreshortening.—When you so place yourself or your lens with reference to any object as to lose the impression of its actual form, so that long objects appear short, or parts become lost to the eye, the effect is termed that of foreshortening. Care should be taken that no portion of the object or figure is so foreshortened as to produce an effect which to all but the more thoroughly educated eye, must convey an impression which would be termed distorted and unnatural. (See *Anamorphosis.*)

Genre-subjects.—Subjects of a certain *genre* or *kind*, which are of a comparatively homely or everyday character, as opposed to those which belong to historical or high art painting are so termed. Such pictures must be regarded as bounding the aspirations of the artist photographer, because the art which soars above these productions immediately enters an existence which is rather dependent upon the loftier imaginings of the mind than the simple imitations of external nature, although upon the latter it, of course, still has its only true foundation. Certain small scarce-fledged critics have derived an immense accession to their puffed-up self-esteem, by affecting to look down upon all art that is not—strictly speaking—high art. But your true connoissieur would rather contemplate a first-class *genre*-subject—hitting full in the eye of its mark—than one of those common and lamentable failures which have fallen so miserably short in an aim rashly chosen by presumption and vanity. The artist photographer may produce subjects of the first-named kind, and if really successful, win for his art the very highest appreciation; but if he think to emulate the poetical imaginings of the gifted painter in subjects which embody the highest order of composition, his fall will be in proportion to the height of his ill-considered aspirations, and the injury done to our little-understood, and much-maligned art, be really greater than if he had confined himself to the most purely mechanical and insignificant departments of his profession. There is plenty of poetry, and that of a lofty character, in those truths of nature which are within the reach of our beautiful processes. There is much to be done for the expression of feeling in our mode of arranging, selecting, developing, and printing a subject. The rules and principles which give value to the imitative production as a work of art can be as well applied to photography; but just in the degree that no mere common-place actor can thoroughly mimick the deeper or more terrible emotions of the mind by simple contortions of the visage or the limbs; just in the same proportion must an art strictly imitative fail to render such in the loftier kinds of composition. Again, the perfection of many fine models may contribute to form the painter's ideal form; but these are so cunningly blended, and harmonized so beautifully, without violation of anatomical consistency, or symmetrical proportion, that it is as impossible for any mere patchwork process of the paste-pot and scissiors to approach such perfection, as for the man who once cut penny black profiles on the London steamboats to surpass with his humble tools the productions of a Raphael or a Michael Angelo.* As I said in a previous article, there is a vast and hardly opened field awaiting the ambitious artist photographer—a field which Wilkie and Teniers did not contemn, and many as eminent in their art have been proud to adorn; but we must not make ourselves artificial wings wherewith to reach the native home of birds which sing at "heaven's gate," or great will be our fall, and loud the laughter of our enemies. Robinson's "Holiday in the Woods"—although faulty—is a most successful and very admirable application of photography to a *genre*-subject, but his Ophelia of the previous year being dependent for its effect chiefly upon the expression given by the model, was a great failure. Rejlander has been *wonderfully* successful in the expressions secured for the faces and positions of his models; but even his most ambitious effort, "The Two Ways of Life," although singularly effective in all other respects, fell, in the amount of the success it achieved, far short of his less ambitious efforts. I therefore advise you as an artist photogropher not to listen to those critics who, to convey lofty ideas of their own reverentially high pitch of refinement and taste, affect in the smart or grandiloquent paragraphs of their critiques to look down upon *genre*-subjects, any more than I advise you to listen to such as endeavour to persuade us that photography has no other bounds in art than such as shut in the greatest genius of the most inspired and educated of poet-painters. If we can't write Milton's immortal epics, there are plenty of sweet little poems whose music is full of exquisite pleasure and loving lessons for the world, which *are* within the reach of our powers, and have not been scorned even by the mightiest of the giant intelects of historical painting.

Glazing.—In Rejlander's very capital and instructive paper upon his photographic picture, "Two Ways of Life," (which, by-the-bye, I do *so* wish the editor would print in these pages†), he tells us, "If there be too much of crude light I will glaze over some parts with the sunbeam;" and describing this method of glazing says, "I cover up some parts of the picture, and use a few *rays* and *pencils* of light to just glaze ‡ over the gamboling group; and, using them a little more freely on the hinder figures, I said 'thank you,' and covered them up—'now please to paint me the back-ground behind them.' The rays do my bidding, and on it goes, smoothly and evenly; I can almost see the fluid flow, and, knowing from practice how it will be reduced in the hypo-bath, I let the light paint it deeper in appearance than it was intended to be. I then uncover the idle group, and bid the light sink one of those figures deeper in the shade. I then solicit the rays to do the same on the side of industry, and many of the spots and marks from the printing of the separate figures are then evened by the same *brush*, and finally the whole top of the picture is exposed; but as such light as I choose works quickly, I must move as fast and guide it well, or there will be marks from his brush." Thus does the sun-light in an artist photographer's hands prove as effective for the purpose of glazing as the hair-brush and transparent pigment of the painter. To use the words of Rejlander once more, "*photography is like a brush full of paint*, USE IT AS YOU ARE ABLE."

* What has become of this once numerous race? I think I recognized one touting at a fourpenny portrait establishment. Has photography swallowed them all up in its capacious maw?

† I do not know a paper which contains more interesting or instructive matter, or one which more clearly proves photography's claim as a fine art. From the time I read it first I felt the warmest respect for and admiration of its author's manly courage, dauntless perseverance, and high artistic talents. Were his paper yet to be read and published I think the photographic world would be much better fitted to appreciate, understand, and apply it than it was at the time it appeared in the Society's *Journal*.

‡ The colours used for glazing are always of a darker tint than the solid colour beneath it; thus, it is said of Apelles, that he glazed with a dark transparent varnish. The processes of glazing are in photography and painting, therefore, essentially the same.

Gradation.—A term not only applied to the tones of the lights and shadows of a picture, when arranged in their natural order, but used also to define the proper subordination of inferior parts in their relationship with the principal. Hence *subordination* is a word sometimes used to express the same meaning. Gradation serves to prevent violent contrasts of tones by intervening or harmonizing extremes. A photograph lacking gradation becomes either spotty and hard, or flat and monotonous in effect. Proper degrees of atmospherical gradation (see *Ærial Perspective*) secures the effect of space, landscape's most charming quality. By gradation of effect is understood the growing impression which leads to or from the picture's chief aim or intention, by other subordinated effects leading gradually up to, or down from, the same. Nature *truthfully* represented must always give gradation,

FAIR PLAY FOR PHOTOGRAPHY.

(*From Punch.*)

SEEING what they weekly have before them in our pages, it is needless to remind our innumerable readers that Art in any shape or form is ever under the protection and the patronage of *Punch.* From the pictures "on the line" at the Royal Academy Exhibition, to the crayon caricatures which are covertly designed on *Mr. Punch's* doorsteps, and wherewith small artists decorate his newly-painted shutters, all works of Art are cherished and encouraged by his influence, and the interests of artists are watched over and secured.

Now *Mr. Punch* has learned from certain of his photographic friends, including his friend, FREDERICK, Lord Chief Baron of England, that HER MAJESTY'S Commissioners for next year's Great Exhibition have thought fit to pass an insult upon Photographic Art, by classing its productions with railway plant and garden-tools, small arms and ships' tackle, big guns and new omnibuses, donkey-carts and corn-extractors, and the thousand other articles of mechanical apparatus comprised in Section II. The Lord Chief Baron, as the mouthpiece of the Photographic Council, has pointed out to the Commissioners that—

"In the observations of natural scenery and in the selection of what shall be represented with reference to the effect of light and shade, and from what point of view, in the grouping and arranging of the principal or accessory objects for the purpose of forming a picture, photography is no doubt an art, an imitative art; but the Council of the Photographic Society claim for it a position, however humble, among the fine arts, if etching and engraving may be so placed, as no doubt justly they may."

In other word, that is, they claim for Photographs a place among the articles admitted under Section IV., which, under the expansive head of "Modern Fine Arts," includes architecture, models, die-sinking, and engravings, in fact (except photographs) anything and everything in any way artistic, from the cast for a new halfpenny and the designs for Guards' Memorials, up to paintings by a MILLAIS and drawings by a PUNCH!

In summing up the case against HER MAJESTY'S Commissioners, the Lord Chief Baron states the grievance of the Photographic plaintiffs in language which, if forcible, is clearly not unfair:—

"The Photographic Society has been founded chiefly with a view to promote photography in connection with science and the fine arts, and the members interest themselves about photographic apparatus in the same manner only as a RAPHAEL or a REYNOLDS might select and use the most convenient easel, the best brushes, or the most appropriate and enduring colours. The instrument is comparatively nothing. * * * They do not complain that the apparatus they use is put among all the other apparatus; but they do complain that results such as have been exhibited for many years by the Society, and have been honoured by the presence and encouragement of HER MAJESTY and H R.H. THE PRINCE CONSORT, are deemed worthy of no better place than among tools and mechanical devices of whatever merit; and they would appeal to the Royal and illustrious patrons of their body to be rescued from the comparative degradation of being mixed up with the last improvement in ploughs or cart-wheels or ships' tackle."

This appeal, *Mr. Punch*, in his Royal pleasure, is pleased graciously to back; and when His wishes are made known to the Commissioners, there will be little need of other "Royal Patrons" to bestir themselves, as His remonstrance will, of course, suffice to set the matter right.

Proceedings of Societies.

THE PHOTOGRAPHIC SOCIETY OF SCOTLAND.

THE fifth annual meeting was held in the Society's Hall, 51, George Street, on Tuesday, May 14th, SHERIFF MOIR, Vice-President, in the chair.

The usual routine proceedings having taken place, and Captain James Grant Suttie having been elected a member of the Society—The Honorary Secretary read the following

REPORT OF THE COUNCIL.

In presenting their Report on the conclusion of the Fifth Year of the Society's existence, the Council would have been glad if they had been enabled to congratulate the members on the past year having been one of more marked progress. Believing, however, that it rests very much with the members themselves, to add not only to the interest of the meetings, but to the usefulness of the society generally, the Council do not doubt but the prominent place, which the society has hitherto occupied, will be fully maintained; and while they trust that before next season they may be able to make such arrangements as will add to the attractiveness of the monthly meetings, they would desire strongly to urge upon members, individually, the many advantages which would arise if they would communicate freely the results of their investigations and experience in particular departments of the Art. Great discoveries are possibly not now to be expected, but still there is an ample field for improvement in all the various branches of the Art,—Chemical, Optical, and Manipulatory; and nothing would form a more attractive feature in the meetings of the society, than the unreserved communication of such details, as well as the exhibition of any new apparatus of which the members of the society may be in possession. While regretting, however, that more has not been done, the Council may fairly congratulate the society on having been the means of giving to the photographic world so many interesting papers as were read before them last year, and published in the *Photographic Journal;* and they desire to record the obligations under which they lie to Sir D. Brewster, Mr. Claudet, Mr. Wall, Mr. L'Amy, Mr. Tunny, Mr. Walker, Mr. Taylor, Mr. Maxwell Lyte, Mr. Cramb, Mr. Burnett, and others, for having contributed them.

At the last Annual General Meeting, the Council had the pleasure of recommending that the Society's Bronze Medal should be awarded to Mr. Macnair, for the account which he had laid before the society of his new dry collodion process. The Council are glad to observe that further experience of this valuable process has completely justified their recommendation. All who have practised it are convinced that it is much the best dry process yet discovered. Its great advantages are the simplicity and certainty of the preparation, the sensitiveness in the camera, and rapidity of development (approaching in these respects even to wet collodion,) the great length of time which it enables the plates to be kept without the slightest deterioration, and the vigour and delicacy of the resulting pictures. Whilst so many new dry processes, or rather modifications of existing processes, are being brought before the public, many of which, by their complication and uncertainty, prove unsatisfactory when tested by the practical photographer, it must be highly satisfactory to the Society to have been the means, through one of its members, of introducing a process which is really valuable and practical.

As the society is aware, the opening of the last Exhibition was postponed from December to February; this was done under the impression that a larger number of visitors might be expected at a season when there are more strangers in town, and the weather is more favourable for visiting places of the kind; the result, however, has not been such as was anticipated, and the Council therefore propose that the next Exhibition should be opened in December, as formerly. The Council are glad to say that, notwithstanding the diminished attendance, the Exhibition will still leave a small balance at the credit of the society; and they need scarcely remind members that in all other respects it was completely successful;—a similar collection in point of merit, more particularly in landscape photography, having probably not previously been brought together.

The two silver medals of the society were this year awarded to Messrs. Claudet and Maxwell Lyte; and on the suggestion of Mr. Horatio Ross, who had again kindly acted as judge, an additional bronze medal was awarded to Mr. H. P. Robinson. It would doubtless be gratifying to the society to see how much the award of their medal is appreciated;—Mr. Claudet having come from London specially to receive his, and both the other gentlemen having expressed in very flattering terms their sense of the honour conferred on them.

Notwithstanding the comparatively unfavourable result of the Exhibition, the funds of the society are in a highly satisfactory position, as will be seen by the annexed state.

It will be in the recollection of the society that it was thought desirable to accumulate, from the annual income, a fund, to be applied in procuring rooms for the special use of the society. From the experience gained elsewhere, however, the Council fear that the great expense attendant on such a scheme, both in reference to original outlay and annual expenditure, places it beyond the reach of the society: accordingly, they would now propose that the society should limit its exertions in this direction, and rather look to entering into an arrangement for acquiring convenient premises along with other kindred societies. As the Council are of opinion that the fund already accumulated should prove sufficient for this purpose, they would suggest that, in future years, a portion of the annual income should be applied in furnishing to each member a photograph, or photographs, illustrative of the progress of the Art; and they would hope that in this way the non-resident members of the society will be enabled to share somewhat more largely than they do at present in its advantages.

As required by the laws of the Society, the President, the Senior Vice-President, (Mr. Horatio Ross), the four Senior Members of the Council, (Messrs. A. Y. Herries, George Harvey, T. Milville Raven, and T. B. Johnston), the Honorary Secretary, and the Honorary Treasurer, retire upon this occasion, but are re-eligible.

The Council would suggest that the President, Vice-President, Secretary, and Treasurer, should be re-elected to their respective offices; that Mr. Herries and Mr. Johnston should be re-elected Councillors; and that Major Ramsay L'Amy, and Mr. Findlay Anderson should be elected in place of Mr. Harvey, who has expressed a desire to retire, and Mr. Raven, who now resides in England.

A state of the funds for the past year is annexed, showing the sum of £386 18s. 11d. in favour of the Society, as compared with £315 12s. 8d. at the close of the preceding year.

On the motion of Sheriff Hallard, seconded by Wm. Walker, Esq., the Report was unanimously adopted.

STATE OF THE FUNDS AT MAY 1, 1861.

	£	s.	d.
Balance in favour of the Society on the General Account, at 1st May, 1861	£380	9	3
Balance on Accounts in connexion with Exhibition and Sale of Photographs	4	7	8
Arrears of Subscriptions due by Members considered recoverable	2	2	0
Amount of Funds as at 1st May 1861	£386	18	11

The following are the officers for 1861-2:—

Patron.—His Royal Highness the Prince Consort.

President.—Sir David Brewster.

Vice-Presidents.—Horatio Ross, George Moir.

Council.—Wm. Scott Elliot, Wm. Walker, C. G. H. Kinnear, John Moffat, Alex. Young Herries, T. B. Johnston, J. Ramsay L'Amy, Findlay Anderson.

Honorary Treasurer.—H. G. Watson.

Honorary Secretary.—A. F. Adam.

Honorary Auditor.—John Cay.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The monthly meeting was held at Myddelton Hall on the evening of Wednesday, the 29th ult. Mr. G. Shadbolt in the chair.

After the minutes of the previous meeting had been read and confirmed, Messrs. G. Elphick and T. Hearn were elected members of the society.

Mr. J. Barnett, honorary secretary to the society, then exhibited a vertical camera of his own contrivance and manufacture, which was intended for copying. He read a brief description paper, as follows:—The idea of making a vertical camera was first suggested to me about twelve months ago, on seeing Mr. W. Hislop attach a portrait camera to the ordinary stand for the purpose of copying geological specimens. The object I then had in view was to produce slides for the magic lantern which should be worthy of our times; and as many of the subjects I desired to possess were prints bound up in different books, I was quite at a loss as to the best means of copying them. Many were too large, others too small, and it was essential to have uniformity in size. A book could not be conveniently fastened against a wall or screen; and, if it could, the grain of the paper was so strongly marked by the side light upon it that it became visible in the negative, and, of course, was reproduced in the printing. The same objection as to fixture applied to plaster medallions, coins, crystals, &c. &c.

I therefore made the camera before you: it is simple, easy of adjustment, perfectly rigid; and, when a print is once correctly focussed, any number of other prints of the same dimensions may be copied, without alteration of camera arrangement, or the slightest chance of the negatives being out of focus. It admits of extension to *twenty-two* inches, and will slide into the body so as to bring the lens within *eleven* inches of the glass screen, so that the object to be copied (if a lens of five-and-a-half inches focal length be used) can be increased to three diameters, or reduced to two-thirds of its original size; and should it be necessary to reduce a large object, it can be placed below the stand, which is left open at the bottom, or it may be used in the ordinary horizontal manner, in which form it is useful in copying glass positives, and other transparent pictures.

The arrangement consists of two perpendicular uprights, fitted in a frame at right angles. Attached to the back of the camera is a slip of oak that runs in a V groove in the uprights, and to fix it in any desired part a screw-bolt and nut is provided, which clenches it so firmly that no ordinary pressure will remove it. The inner, or sliding-box of the camera is similar to that in general use, with the exception of being lengthened by a tube, with the lens attached, or rather sliding in a V groove at its base, so as to admit other lenses, or a combination, according to the work to be done.

The manner of focussing is thus performed:—if the object is to be enlarged, draw out the tube to some extent, and fix with one of the side screws, of which there are six—three on each side; then draw up or lower the camera on the uprights until the focus is clear: if not large enough, draw the tube out further, fixing as before, and so proceed until the exact size and desired sharpness is obtained, then fix in position by the screw-bolt at the top. If it should be necessary the fine adjustment of the lens can now be used. To reduce an object I find it best to slide the tube up to its full extent, and draw out if necessary.

You will perceive there is but one slide, and that the dark one: it carries the ground-glass, which is removed for the prepared plate to take its place. One great advantage in this is the certainty of obtaining a picture in the exact focus it appeared on the screen; and, however carelessly the apparatus may have been made, you will not experience the annoyance so often felt at finding your picture less sharp when taken than it appeared on the ground-glass.

I am desirous it should be distinctly understood that I make no claim to originality in the formation of this camera. I have only done a little towards maturing the method adopted by Mr. Hislop; and should any friends feel disposed to follow out the *principle* here adopted for copying purposes, they will find an immense saving of time, and I doubt not we shall have some pleasing results placed upon the table at our next meeting.

Mr. MOENS asked if the camera being above the object to be copied did not prevent the light falling properly on it.

Mr. BARNARD had not found in practice that it did so at all.

Mr. BARBER asked what was the especial advantage in the vertical shape.

Mr. BARNARD said, that the light striking the paper vertically instead of from the side, the grain or texture of the surface was much less apparent.

Mr. BARBER thought that a similar effect might be obtained by placing the camera in such a position that direct light from the window did not strike the picture to be copied, but only diffused light of the room.

Mr. BARNARD said there were other advantages; the engravings he wished to copy were chiefly in books, and this camera offered facilities for copying them without removal from the books.

A conversation then arose on the subject of the best wood for cameras, &c., the Chairman observing that he was glad to see that Mr. Barnard had used deal for his camera. He had not, however, selected the best kind for that purpose; it should have Christiana white deal, instead of Quebec white pine, which, although light, would not stand so well.

Mr. SHADBOLT then vacated the chair and read some remarks on the mounting of stereographs, of which the following is an abstract. He said that corresponding points in a pair of stereographs, viewed through a whole-lens stereoscope, should be placed at such distance apart as equals that between the eyes of the observer; but, if viewed through a prismatic stereoscope, the separation of the corresponding pictorial points should be augmented by the amount of lateral displacement. Now, there being two variable quantities involved—viz., the width between the eyes of different observers and the lateral displacement of rays by the prisms used—it was necessary to ascertain something like an approach to an average of the amount of these inconstant quantities, and, after careful consideration of the matter, he had fixed it at 2·75 inches. He had measured the distance in a large collection of Wilson's gems, remembering that when they are viewed in one of Smith, Beck, and Beck's achromatic stereoscopes, they produced an effect suggestive of natural size and distant view. The distance between similar points was very constant, being 2·8 inches, differing only *five-hundredths* of an inch from the standard which he had adopted.

As the field of view in a stereograph was necessarily more contracted than in nature, the illusive effect produced was improved by so mounting the pair that we might appear to be regarding the view *through an aperture* not very distant, which limits the amount of subject seen. In such a case actually occurring, the right eye could see rather more of the left side of the view, and rather less of the right side than could be observed with the left eye, and *vice versâ*. To give an illustration:—Suppose a person standing near a small window, looking into a garden, and perceiving in the centre a fountain, and an avenue of trees, at regular intervals, stretching away from the fountain on either hand. Now, if he closed the left eye, keeping the head still, he would find that the vista included three trees on the right side of the fountain, and four on its left side. Now, on opening the left, and closing the right eye, still keeping the head in the same position, he would find that the left side of the fountain had but three trees visible between it and the window frame, while there are four in the space on the right side.

It was therefore clear that—although the right and left pictures each included the same amount of subject—though eight trees were visible to the observer only seven of them were seen by either eye. Therefore, if in mounting stereographs they bear this fact in mind, and cut the pictures in accordance with this principle, the illusory effect was materially improved; because then the mounting card (which should be of an unobtrusive hue, such as black, grey, or drab) acted like a diaphragm, appearing near at hand, while the landscape in the photograph seems to recede from the spectator.

Assuming that $2\frac{3}{4}$ inches was the intended distance between corresponding points of the pair of pictures when mounted, let

a | R *b* | L | *c*

represent a negative taken by a bi-lens camera on R and L, the corresponding points. They must cut the proof so that the distance *a* R, added to L *c*, would together make exactly $2\frac{3}{4}$ inches; but it was also needful, at the same time, to arrange so that the distance *a* R was greater than *b* L, and that *a b* and *b c* was equal. The amount of variation was of minor importance; but if too great, say exceeding a quarter of an inch, the effect would not be pleasing. The above precautions also involved the fact that R *b* is less than L *c*. In conclusion we observed that it was not needful that the sum of *a* R and L *c* should amount to $2\frac{3}{4}$ inches, provided that it did not exceed it, *and* that when transposed, a space be left between the margins *a* and *c* (which would then be contiguous), so that the points L and R are exactly $2\frac{3}{4}$ inches apart.

Mr. DAWSON referred to the method adopted by Mr. Russell Sedgfield, which was explained more at length by

Mr. HUGHES, who stated that Mr. Sedgfield's object was to secure uniformity and good results with as little trouble as possible; he therefore so arranged his negatives as to aid this end. If the negatives were taken with a bi-lens camera, they were cut in two, and bound together in the required position on to another plate of glass, so that the pictures when printed required no cutting. A mark or marks were made on the negative through which pins were run in the prints, which were thus arranged so as to cut three dozen at a time, both halves of the picture at once, which was not divided in the middle. They were cut by means of a steel shape and a press something like that used for stamping the impressions of dies on envelopes; the pressure being obtained by means of a screw and lever which was sent spinning round by one rapid turn of the hand.

The Chairman called attention to some exquisite groups of flowers photographed and presented to the society by Mr. Mainwaring.

Mr. Barber showed some negatives by the resin process. He had at first tried it with his ordinary nitrate bath, which probably contained a little nitric acid, and got nothing but fog and stains; but had since tried it with a fresh bath, to which he had added about two or three minims of acetic acid per ounce, and the result was good clean negatives. He had not, however, noticed that the plates possessed especial sensitiveness.

A conversation on the subject followed, in which several members took part, the Chairman observing that the re-dipping in the nitrate bath, which Mr. Barber had omitted, was insisted on by the advocates of the resin process, as a point vital to rapidity, or shortness of exposure.

Mr. Hughes alluded to the simple dry process to which Mr. Hannaford had recently been calling attention, and regarding which he had heard many good accounts; he referred to the addition of silver to the albumen solution. He knew a gentleman who had long successfully practised the Taupenot process, who was thinking of giving it up for the new method.

Mr. Barber suggested that the preparation of an ammonia-nitrate solution, and adding it to the albumen, would be a more simple and philosophical method of proceeding about the matter, than the addition of nitrate of silver to a solution of albumen containing ammonia.

After some further conversation on the subject, in which the Chairman observed that he had received communications from several correspondents, speaking highly of the process, the subject dropped.

Mr. Shave asked if any one knew anything of the new process which was to abrogate the necessity for a silver bath.

Mr. G. Wharton Simpson said he had himself produced negatives by the process, but they were not all that could be desired, having a tendency to be thin in the lights and veiled in the shadows. He was not aware whether Captain Dixon, the inventor, had made any more progress with it; but he believed the matter remained, at present, in a state of *statu quo*.

The Chairman then stated that the committee had resolved to recommend that the monthly meetings should in future be held on the last Wednesday but one, instead of the last Wednesday in the month, which suggestion was accepted and agreed to by the meeting.

The proceedings then terminated.

London Photographic Society.

The monthly meeting of the society was held at King's College on Tuesday evening, Joseph Durham, Esq., in the chair.

The meeting was held on this occasion in the theatre of the college to afford a better opportunity of exhibiting Professor Way's electric light, as announced by Mr. Vernon Heath at the last meeting.

After the minutes of the previous meeting had been read the following gentlemen were elected members of the society:—Earl Cawdor, R. C. Oldfield, Esq., and Major Shakspeare.

Mr. Vernon Heath, in pursuance of a notice at the last meeting, made some remarks on the anomalous position in which it has been proposed to place photography at the forthcoming International Exhibition. His task, he observed, was very much simplified by the forcible and appropriate letter of their excellent president. He might now content himself, therefore, by asking the chairman to detail to them what had occurred since. At all events, whatever answer that letter might receive, he felt sure that the spirit of the president's letter, and the manner in which the council had taken the matter up, were both such as to deserve their warmest and best thanks. He would not now detain them by entering further into the matter, as the Chief Baron's letter quite exhausted the subject. He would just ask the chairman, therefore, to state to them the present position in which the matter stood.

The Chairman said the best thing would be simply to call upon the secretary to read the minutes of the various meetings on this subject held by the council, and the correspondence which had passed between the council and the commissioners. By this means the meeting would be put in possession of the results as they at present stood

The Secretary then read the minutes of the meetings of the council, referring to the subject, and the correspondence into which they had entered regarding it. The results up to last week our readers are already familiar with. Since then the commissioners have answered the Chief Baron's second letter to which we have referred, and decline to receive the proposed deputation from the society. The council had again met that day and come to certain conclusions which they did not deem it prudent at the present stage of affairs to communicate. A letter which they had received from Dr. Lyon Playfair was also read, in which he strongly condemned the proposed classification, and maintained the right of photography to be classified amongst the fine arts, observing that engraving might, with equal propriety, be placed as a sub-division under cutlery, because it was produced by edge tools, as photography classed with the apparatus necessary to its manipulations.

Mr. H. G. Bohn said he was chairman of one of the sub-committees of the Exhibition of 1851. If he remembered rightly he shared a department with Mr. Owen Jones, and photographers were then admitted as belonging to the fine arts; being placed, if he mistook not, in the same category as colour printing.

Mr. Malone called Mr. Bohn's attention to his remarks on this subject at the last meeting, in which he stated that photographs were denied the claim to be placed amongst the fine arts.

A conversation on the subject arose in which Mr. Bohn remarked that he had only referred to what came under his notice in his own department in the gallery. Mr. Malone might be quite correct as to what took place in other departments. It further transpired from the chairman that it was not improbable that a special meeting of the members might be called to determine what steps should finally be taken in this matter.

Mr. Shadbolt referred to the cool assumption contained in one of the letters of the Commissioners, that a committee would be appointed to co-operate with them, when the Chief Baron had distinctly stated that no such committee would be appointed unless Photography was placed in its legitimate position.

The Secretary called attention to some specimens by Mr. Bedford taken for the purpose of testing one of Ross's orthographic lenses.

Mr. Bedford stated, that the lens had been especially tested in reference to an alleged want of what was termed depth of focus. He had tested the lens very severely, inasmuch as he had taken the negatives upon a 12in. by 10in. plate with a lens only intended to cover 8½in. by 6½in., or ordinary whole plate. The interior, one of Ely Cathedral, was exposed five minutes with the full aperture, and taken on a wet collodion plate. The exterior of the same building was exposed eight seconds with a stop of $\frac{1}{75}$ of an inch. The results were, he thought, under the circumstances, very satisfactory.

Mr. Shadbolt had in his hands some prints from negatives taken by the gentleman who had stated this lens was incompetent to do its work; two of the pictures were by this lens, and called defective; and other two exhibited as pendants to them, and called analogous for testing purposes. Now the subjects were so dissimilar, and unfair as tests of the relative qualities of any lens, that he unhesitatingly said the man who called them analogous was incompetent to test any lens. Regarding this quality of so-called depth of focus, a lens possessing it was as bad a lens as could be. The phrase itself was an absurdity, and was only used by opticians who did not know their work, or who wished to deceive the public. It was impossible to have objects in different planes all equally sharp; and what was termed depth of focus, was simply destroying all focus, and making the definition of every part equally bad.

Mr. Sutton said there were *two* kinds of depth of focus: that produced by a bad lens with large aperture, and that produced by a good lens with a small aperture. They were two essentially different things: the one a desirable quality, and the other undesirable. Mr. Shadbolt seemed to confound these two things together.

Mr. Shadbolt said there was no such thing at all: it was altogether a myth. The only effect of using a small aperture was, that objects out of the focal plane were not quite so much out of focus. The light entering at a more acute angle when the small stop was used, a section of this acute angle did not cause such a large blot or blur as it would if it were a more obtuse angle. In other words, the circle of least confusion was more easily ascertained when a small aperture was used.

Mr. Malone said with regard to a single lens with a full aperture there was, absolutely speaking, no depth of focus at all; and so far, theoretically speaking, Mr. Shadbolt was right. But he also agreed with Mr. Sutton that we must look at the question practically, and in relation to the necessities of photography. A lens might give what was termed depth of focus, and that depth might arise from its being in a certain sense a bad lens; but nevertheless its results might be admired. He knew a portrait lens of such a character, and it gave very good and pleasant portraits; but he believed, notwithstanding that, it would be regarded from Mr. Ross's point of view as being very faulty. There was no absolute or mathematical focus anywhere. It was an important point to select a lens in relation to its purpose. If it were always necessary to stop down a lens very much in order to secure the required depth, it was often at an inconvenient sacrifice of light.

Mr. Shadbolt thought Mr. Malone had availed himself of the French philospher's maxim, and used language to conceal his ideas.

Mr. Sutton said, if there were no such thing as depth of focus, it would be impossible to get a photograph fit to be seen. He should like to know what Mr. Shadbolt called that quality which rendered the retiring objects in a picture at all tolerable.

Mr. Shadbolt simply denied that it was possible to get two objects in different planes at the same time. It was impossible to get one in, without the other being more or less out.

Mr. Sutton said it was quite possible to give sufficient definition to all objects within a space of from twenty-five yards to a mile or two.

Mr. Shadbolt: Simply because in that case there was no object in focus.

Mr. Sutton: Oh yes—as fine as possible.

The Chairman thought there was far too great a tendency on the part of photographers to tie lenses down to do one thing, and if it exceeded that it was proclaimed to be bad photography. It might be so; but it was good art. He had seen such landscapes and such portraits, which some would say were not perfect photography. But they were such views of nature as some of the greatest masters in art, such men as Raphael, Claude, and Teniers, had seen, and pourtrayed, and considered right; and if it were bad photography it was beautiful art. He was sorry to be compelled to say it; but artists loved those things which many photographers called bad. Such photographs were very rare, but were prized by artists as treasures when they could be obtained.

Mr. Shadbolt denied in toto the Chairman's remarks as referring to photographers and artists. He had stated that no lens could produce two different planes in absolute focus at the same time, and in saying so he had merely affirmed of a lens what was true of the human eye, and he contended that it was true art to produce a picture similar to that formed on the retina of the eye.

Mr. Malone said he had been charged with want of clearness by Mr. Shadbolt—he just wished one or two words more to make himself clearer. He remembered some years ago a large lens of five inches in diameter, made by the late Mr. Ross, which he had to test. On trying it out of the window at the opposite side of the street, they found they could not get the bricks of the opposite house and the railings which sursurrounded it into anything like focus at the same time, and when they complained of this to Mr. Ross, he said he thought they were very unreasonable to want such a thing. When, however, they took a small lens of six inches focus and tried it, that gave the result meant by depth of focus; both the railings and the bricks were sufficiently defined without sacrificing either. He believed a more perfect picture of the subject would have been obtained by taking it with the small lens first and then enlarging, than by taking with the large lens direct.

Mr. Vernon Heath then proceeded to read a paper descriptive of the Professor Way's electric light and its applicability to photographic purposes.

This light, which is considered to possess more of the photogenic rays than any other artificial light, has been more than once described in our columns. Its exhibition excited considerable interest, which was enhanced by the exhibition, for the purpose of comparison of Duboscq's electric lamp. The latter possesses simply the illuminating qualities of a very brilliant artificial light, whilst the mercurial light of Professor Way, from the striking absence of any of the red rays, is very peculiar in its illuminating effect. Every countenance appears of a most ghastly hue, which, together with the purple lips, suggests that the spectator has suddenly visited a lazar house, or plague-stricken community, whilst everything else, almost, appears other than it was a few minutes before.

Printing in the printing frame and by means of the solar camera were conducted before the meeting. The details and discussion thereon we must, for lack of space, reserve for another week.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 5th June, 1861.

Positive printing on albumenized paper appears to command increased attention just now, and justly so, for while nearly every other element of photographic success has arrived at a state, if not exactly of perfection, at least at a very satisfactory approach to it. But what avails all this, if positive printing remains in a state of uncertainty? if the fruit of all our previous care and labour must ultimately disappear and perish? Mr. Maxwell Lyte has recently given us the benefit of his experience, and proposed formula, which it is to be hoped will secure to the photographer such results as may defy the inroads of time. Now, the Abbé Pujo has undertaken an investigation of the phenomena of positive printing, more especially with regard to the nature of the compound of albumen and nitrate of silver, commonly described as albuminate of silver, which appears to play a very important part in positive printing, the details of his investigation are very interesting; but as they are too lengthy to be comprised within the limits of a letter I must send you a separate communication, which I doubt not will deeply interest such of your readers as take an interest in the philosophy of positive printing.

M. Becquerel's researches upon electro-chemical colouration, and the deposit of peroxide of iron upon plates of iron and steel, are not without interest to photographers. His aim was not to produce coloured rings like those of Nabile (1827), but to deposit on plates of gold, platinum, silver, copper, and other metals, thin and uniform coatings of peroxide of lead, presenting in succession, according to the duration of the operation, which is generally very short, the rich colours of the spectrum. Into an alkaline solution of protoxide of lead he immerses the pieces of metal to be coloured, putting it in connection with the positive pole of a nitric acid pile composed of several couples; he then closes the circuit with a platinum wire in communication with the negative pole, the point of which alone touches the alkaline solution, and is kept constantly in motion. The protoxide of lead in contact with the object to be coloured, which forms the positive electrode, is superoxydised, becomes insoluble in the alkali, and deposits itself upon the surface in thin films with the production of colours, which are adherent. These colours become gradually weaker by contact with air and light, unless covered with spirit varnish, which acts only very feebly on the peroxide. With a little practice we can soon succeed in giving every desirable tint to an object of large dimensions of irregular surface, which, it may be said, can be painted in appropriate colours. In what manner these colours may be rendered permanent will be explained hereafter.

By substituting a solution or protoxide of iron in ammonia for the solution of protoxide of lead in potassa and a plate of polished iron in lieu of the plate of gold, platinum, copper, or silver it deposits upon the latter a film of peroxide of iron with brown red tints which deepen more and more as the film becomes thicker.

In precipitating metals from their solutions by other more oxidizable metals, M. Becquerel remarks that upon immersing a plate of copper in a solution of double chloride of potassium and platinum, heated to 100° Fahr., we perceive it to become covered with a film of adherent platinum, thin, and brightly coloured, but which gradually alters and becomes brown in the atmosphere. This change is partly due to the presence of protochloride of copper which is deposited with the platinum towards the end of the operation. On washing the platinized copper with water acidulated by acetic acid, or in rubbing its surface with cotton and colcothar, the protochloride is removed, and the change ceases, or at least manifests itself only after a very long time.

If platinized copper is employed, at the moment it is removed from the solution of double chloride. as the positive electrode to decompose water with a pile composed of a few elements, it produces, under the influence of the oxygen disengaged from the positive pole, some effects of colouring characterized by a deep crimson blue tint, which does not yield the protochloride of copper altered by light, and which is unchangeable in the air.

If for decomposing water we employ, as a positive electrode, a plate of copper covered with a film of peroxide of lead yielding one of the pure colours of the spectrum, we find that at the end of a few moments, the colour is preserved. In allowing the electro-chemical action for a quarter of an hour, or half an hour, according to the strength of the pile, the violet and blue tints become weaker, and change to green and yellow. When upon a plate of gold or platinum, we deposit electrochemically, by means of a solution of double chloride of potassium and platinum containing no copper, a very thin film of platinum, this film undergoes no change either in the atmosphere, or when the plate is employed as a positive electrode to decompose water; it is not so when the solution contains copper; we then see it produce the colouring effects previously described; when the proportion of copper is very feeble, diluted nitric acid does not destroy the colour on the platinum, which is a very great advantage in application.

The solution of double chloride of potassium and platinum in hyposulphite of soda, gives magnificent effects of colouring.

The deposits of peroxide of iron upon iron and steel, which, almost unchangeable in the atmosphere, become so when the plates have been employed as positive electrodes to decompose water.

M. Becquerel has presented some specimens of this new art to the Paris Academy of Sciences, where they excited much admiration.

ART PHOTOGRAPHIC SOCIETY.

Dear Sir,—The discussions now in progress between the advocates of photography as an art, and Her Majesty's Commissioners for the next Great Exhibition of 1862, induce me to trouble you with a few lines on the subject.

It must be remembered that until quite recently this country has not been at all distinguished for the slightest display of interest in the development and cultivation of artistic taste or knowledge. While universities were giving full and free opportunities for the study of the principles, practice, and theoretical elements of art in all the more highly educated countries of the world, England appeared rather to regard such branches of tuition as a fanciful luxury, fitted only for the leisure and refinement of aristocratic wealth and taste; for, from the humblest school, upwards to our colleges and universities, the culture and study of art was, even in its simplest elements, thoroughly neglected.

What wonder then, when a picture-producing agent was placed within the creative power of all who would patiently master its first mechanical difficulties, productions which, for truth of outline and perfection of detail, surpassed the best works of the greatest painters, that this new art should so soon be buried, as it were, beneath a mountain of productions displaying the most perfect ignorance of artistic rules, principles, and theories?

That this was true of photography, all artistic observers must confess, and that this does not seem likely to continue true, is due to the efforts of the few who, like yourself, labour to create a just feeling and regard for art among the practitioners of photography, rather than to those older established journals and societies who have so culpably neglected this essential element of the new arts' upward progress. That such journals and such societies are losing ground, or becoming extinct, must be attributed to their misconception of the characteristics and scope of the art they are supposed to advance.

That photography does not rank as an art in public estimation, and that Her Majesty's Commissioners class its productions with its apparatus and processes as requiring an equal amount of intellectual culture, seems to me, under existing circumstances, the most natural thing in the world. I therefore very cordially agree with "one who likes small deeds better than large words." We *do* want a photographic society which shall make the art element its most prominent feature, and I, for one, should be happy to co-operate with others who may think such a want should and could be supplied. There is a very extensive field open for an active and enterprising first class society, which will not be content to assume no more importance, in connection with the advancement of the art, than that of a small social club of idle members whose proceedings merely assume the form of light or frivolous impromptu gossiping about the minor details of an apparatus or a process. I do not see the slightest reason why such a society should not become a really elevating representative of the art. There are many able gentlemen who, having lost all hope in the active utility of the present society at King's College, might, I feel sure, be confidently looked to for assistance; and there are many others who feel that the meetings of smaller societies, however friendly and social they may be, are wanting in the earnestness and dignity essential to greater and more important ends.

My object in writing is to lay before your readers the above views and suggest that such of them as agree with me in desiring the formation of a photographic society of England for the elevation of photography as an art, and consequently as a science, should forward their names, directing such communications to the office of the Photographic News. I enclose my card, and am, dear sir, yours truly,

A Photographer and Artist.

AMATEURS PHOTOGRAPHIC ASSOCIATION.

Dear Sir,—Whilst the Amateur Photographic Association has elicited an outburst of approval far exceeding the most sanguine expectations of its projectors, some few objections or queries have reached me, which deserve, I think, to be noticed.

I will, for the sake of brevity, put them in the form of question and answer.

Objection 1.—Is it just that the prize negatives shall become the property of the publishers when the prizes are paid for by the Association?

Answer 1.—The prizes are *awarded* by the *Committee*, but *paid* for by the *publishers*. This objection, therefore, falls to the ground.

Objection 2.—Is it not an anomaly to declare that "none but amateur photographers shall be admitted as members," or in plain words to exclude the profession, whilst the fact is that as soon as a photographer takes to selling his pictures he becomes a professional, for professionals do no more?

Answer 2.—This objection I have placed in the strongest possible light, and it is exceedingly plausible; for although we well *know* the difference between an amateur and a professional photographer, yet it is difficult so to define the terms as not to lay oneself open to criticism. Suffice it, however, to say, that whilst an amateur photographer is one who is wholly independent of photography, but practises it for the love of it, and who will love it none the less should he find that the public are glad to purchase copies of his pictures at such a price as to make his amusement self-supporting. A professional photographer is one whose income upon which he depends is derived wholly or in part from the practice of the art.

Objection 3.—Will not the selection of prints, the choice of negatives for publication, and other matters connected therewith, be apt to engender feelings of dissatisfaction or even mortification?

Answer 3.—It cannot be expected that a scheme so complicated and comprehensive will be altogether free from difficulties; and if the rules are somewhat vague on certain points, it is because it is thought that there are matters which will be better left to the judgment of management and the committee of referees, and the public may well rely upon it that they will act with an impartiality above suspicion, that in no case need members select pictures inferior in quality to the negatives which they send, and that justice and liberality will be shown to all. In conclusion, Sir, allow me to add that although (as you well know) no thought nor labour has been spared in drawing up the rules, yet we do not pretend that the thing is yet perfect; but we do confidently believe that it is so substantially good that we may reasonably hope to make it so.—I am, dear sir, very faithfully yours, A. Melhuish, Hon. Sec.

P.S.—Since writing the above I have received a letter from the chaplain of H.M.S. ——, in which, after characterizing the association as "the very thing we have long wanted," the writer asks one or two questions which suggest to me that it may not be unnecessary further to mention that the publishers alone are responsible for all expenses incurred, and no member can, under any circumstances, be called upon for anything beyond his yearly subscription, which, as usual, is payable in advance.

Photographic Notes and Queries.

Various Queries.

Sir,—You will oblige an old reader of the Photographic News by giving a reply to the following queries:—

In No. 138, referring to the new process by Capt. Dixon, you stated the preparation was just going to be patented. Is the specification completed? If so, will you give your readers a copy, or is the preparation for sale?

2. In No. 141, you refer to a new dry process by Rev. L. Sisson. When are you likely to give full particulars?

3. Mr. Joubert some time ago stated that so soon as he had matured his process he would give to the photographers of England full details; is there any word of his doing so? If not mature why advertise for printing by an incomplete process?

4. In preparing an iodizer for my plain collodion, I use occasionally one or other of the following:—Iodide potassium, 2 grains, iodide cadmium, 2 grains, bromide cadmium, 1 grain, chloride cadmium, 1 grain: or iodide potassium, 4 grains, bromide of calcium, 1 grain, tincture of iodine, 1 drop; are these good for positive collodion, or will you oblige me with a better?

5. In 1851, without consulting an experienced photographer, I purchased a full plate combination lense for portraits and views 3¼ inches diameter, made by Lerebour. Finding myself unable to obtain facilities for taking portraits I have for a long time spent leisure in copying engravings and taking instantaneous views from the window, using a small stop of one inch; still I am not satisfied. The picture, somehow, is far from being sharp and is much out of focus; some distance from the edge I have tried various proposed plans to obtain a flat field sharp picture without losing light, but ineffectually. Can you help me? or is my lens, being not so good as at present made, likely to require me to sell and get one better suited? By using a small concave lens midway with lenses I obtained a large field and flat to the edge, but the picture on the ground glass appeared misty and not sharp.

6. Mr. Crookes in the early No. 8, page 86. Photographic News, referred to a new metal discovered by Sir J. Herschell, called Junonium, which promised to rival silver. Can you give any information on this point?

I have troubled you on a number of points, but I believe all less or more of interest to amateurs, &c.—Yours truly,

Glasguensis.

Glasgow, 4th June, 1861.

[1. The process is patented. Specifications are never accessible until they have been lodged six months. We believe the process is not yet sufficiently perfect to warrant the sale of the preparation. 2. As soon as sufficiently tested. We hope shortly. 4. M. Joubert stated that he would make his process known when it was sufficiently matured to be placed safely in anybody's hands, but that at present it required nice skill to work it creditably. That skill he can secure under his own superintendence, but it might not be found in everyday manipulators. You must distinguish between an incomplete process and one requiring more than average skill to work it successfully. 4. Either of your formulæ are well suited to positives; but unless you have much water in your alcohol you will have an undissolved precipitate in the collodion from the second formula. With potassium as the only base of the iodizer it is difficult to get much of a bromide into the collodion—in our only experience barely half-a-grain to an ounce. A little tincture of iodine would probably improve the first formula. We apprehend the whole of the chloride is not dissolved. 5. Regarding the lens it is very difficult indeed to give an opinion without seeing its work. The manufacture of photographic lenses has improved very much since 1851, but Lerebour is a good French maker. You cannot gain much by introducing any other lens at random. Probably you would do well to sell it and get another. 6. We have not any recent information regarding the metal referred to.—Ed.]

Developing Box.

Dear Sir,—I have just made for my own use a plain, useful, and inexpensive developing box for out-of-doors photography. Thinking some of your readers would like to make a similar one. I beg to offer the following description of it.

The box is of half-inch deal, 26 inches long by 13 wide, and 11 inches deep. Through the bottom on the right-hand side is a hole 10 inches by 4 inches, through which my box holding the bath drops level with the bottom; at the back is a square of yellow glass, 10 inches by 4 inches; at each end a circular piece of the same 4 inches diameter; in the front are fixed two sleeves with elastic bands to close tight to the arms and exclude white light.

The lid is made to fit on without joints, and I have a square of yellow glass fitted in a frame in the top of the lid to see through, and made loose to prevent the necessity of taking the lid off for changing plates and taking the dark slide out. I have a black cloth tacked to the back of the box to cover the head while working. The box stands on three legs, two at one end and one at the other, which screw into blocks at the bottom and pack inside the box when out of use. Over the whole I have a cover made of American cloth and a handle at each end for convenience of carrying.

It will hold all necessary things, such as camera, folding stand, plate, boxes and chemicals. C. S.

P.S.—The whole cost of the above I think would be under 10s.

[One of your old correspondents, Mr. Barrett, of Reigate, recently showed us a very convenient operating box for the field, which, in many respects, resembles the one here described. We hope to describe it shortly.—Ed.]

The Fothergill Process.

Dear Sir,—I would advise all who want a good and certain *dry* process to use the Fothergill process as practised by Mr. Howard, which was published in the News a few months ago. I had tried almost every dry process with their several modifications without any great success, and was almost giving the dry process up in despair, when, seeing Mr. Howard's manner of working, I determined to try once more, and I am glad I did. I began with great care, and attended strictly to having every thing in the most perfect order. The collodion I use is some I prepared myself last summer, and which I set aside, after trying, as useless. I can go out on Saturday afternoon with my dozen plates in a *deal* box lined out with brown paper, and the Photographic News in my pocket, and read away while a plate is being exposed, feeling as happy as a photographer ought to (when he feels *assured* that his dry plates will turn out well). I send you three specimens of views from dry plates.

I find that one of the *greatest* causes of blisters is imperfect washing after the albumen is applied. Now last week, while preparing some dry plates, I inadvertently omitted to give a plate three washings (Mr. Howard's manner) only giving it one, and, on developing, it became covered with blisters.

I have tried Mr. Hannaford's modification with perfect success; but not having any prints finished, of course I cannot forward any at present. The plates I operate upon are stereoscopic.
Yours obediently, Teesdale.

[Our correspondent's prints suggest that he will become a worthy pupil of Mr. Howard.—Ed.]

Talk in the Studio.

Photography and the Exhibition of 1862.—The *London Review*, speaking of the proposed classification of photographs amongst cart wheels, &c.: "We can imagine a commission composed of men having no more acquaintauce with photography than can be gained by looking into shop windows, placing a photograph in the third class, by the side of woven fabrics, lace and embroidery, paper-hangings, and papier-mâché; the "tea-board" style of art exhibited in some photographic perpetrations being about as artistic as the ornamental design on a papier-mâché tray; but what possible confusion of ideas in the minds of the Commissioners could have led them to class a photograph as a tool. In any case it is a *result*, and as such the Commissioners are bound by their own classification to place it along with the other results of machines acting upon the raw material, even if they refuse to give it admission among the Fine Arts. As it at present stands, it is the only exception in the whole classification. it is the only result involving intellect and design, which is degraded to the level of the machine used in its production. The very paper and glass upon which a photograph is taken is ranked as more worthy than the finished *picture*. The incongruity is as great as if a painting by Raphael were placed below brushes and colours, or as if the Venus di Medici were exhibited as a raw material, by the side of a block of marble of less importance than the chisel and mallet used in her sculpture."

Photography made Easy.—Among the numerous handbooks, which are to do so much for us in this world, such as cure "all the ills that flesh is heir to," make our fortune, marry us happily, &c. &c., one is now published according to the well-circulated handbill, now before us, by which "any careful person may, the first trial, produce a good photograph as certainly as a carpenter can produce from wood a stool or chair." We may as well therefore remind the gullible that even to produce a stool or chair requires some skill and experience, and that even carpenters do not become such without an apprenticeship.

Adulterations in Paper.—Two correspondents of the *Times* have recently called attention to the serious extent to which the use of earthy matter has been used in the manufacture of paper of late years, both by English and Continental makers. As much as thirty per cent. of white clay, and other earthy matters, amongst which are silica, alumina, &c., have been detected in samples professing to be of good quality. How far these substances are present in photographic papers, and how far many of the printing troubles of the photographer may be due to such adulterations, we cannot here enquire. But the subject is worth attention.

Dropping Bottle..—We believe many pictures are spoiled in development, from the uncertain amount of silver added to the developer. An attempt is made to pour a few drops from the lip of an ordinary bottle, and possibly four drops fall, and quite as possibly a little stream containing twenty drops. To remedy this difficulty, a dropping bottle should always be used, by which a definite quantity can be added, and the number of drops regulated absolutely. We have received from Mr. S. Highley a neat and convenient dropping bottle of his invention. It consists of a stoppered bottle, in the stopper of which is a capillary aperture which admits readily of the discharge of one drop of the contents at a time, and no more. To prevent evaporation, and the clogging of the aperture with dust, &c., a cap fits over the stopper. The whole is neatly packed in a turned wooden case, which permits it, no matter what its contents, to be carried safely in the pocket. Another use for which this bottle is admirably adapted, from the precision with which it discharges a drop at a time. is for adding nitric or other acid to the bath, an operation in which excess is fatal. The bottle is manufactured by Mr. Eve of Holborn.

Grand Historical Picture of Garibaldi.—Mr. Barker's great "sensation picture" of Garibaldi was, we understand, entirely painted from photographs. Some critics state that Mr. Barker's painting is less true to nature than the photographs which formed his studies.

Birmingham Photographic Exhibition.—The opening of the Exhibition at Aston Hall, has been delayed longer than was intended. The arrangements are, however, rapidly in progress, and it is hoped that the Exhibition will be fully opened shortly. We shall give some particulars of the pictures exhibited in an early number.

To Correspondents.

T. Y. K.—Your prints are simply not fixed. An immersion of one minute would scarcely be sufficient to fix them, even if you used a saturated solution of hypo, much less a solution only containing one part of hypo to twelve of water. Use a much stronger solution, not less than four ounces of hypo in a pint of water, and let the print remain in at least ten minutes. In order to prevent the hypo turning the print too red let it remain in the gold toning solution a little longer. You must wash, moreover, for as many hours as you have done minutes.

A Poor Photographer.—You can make oxide of silver in the way we have described from a portion of an old bath. You do not state whether you are working negatives or positives; but from your remarks we infer the latter. If so, the free addition of nitric acid, say half-a-dozen drops to a pint of solution might possibly meet your case. Try that, as it is easily neutralized with oxide of silver, afterwards, should it not remedy the evil. Should it fail to do so, then you may add oxide of silver and place the bath in sunlight, and afterwards filter and add nitric acid a drop at a time until the bath works properly.

Robert Thomas Wright.—Any grease which may be in the inside of the worm of your still will be removed by washing with a warm solution of common washing soda, and then rinsing well. The presence of grease would be very easily seen floating on the top of the distilled water. You may easily test the water by adding a little nitrate of silver to it. If you have any doubt about it, add a little oxide of silver to the bath when you make it, and place the solution in the light. Any organic matter present will be blackened and precipitated. Then filter and acidify as may be necessary.

J. P. C.—Possibly your printing bath is alkaline, which would favour the rapid discolouration of paper. In that case add a little citric acid, or a drop or two of nitric acid. Moisture in the atmosphere where the excited paper is kept favours the rapid discolouration; therefore the paper should be kept in a dry place after exciting. If you cannot tone prints immediately after printing it is better to keep them in a drawer or box in a dry place until you can, than to keep them many hours in water. Gas burning in the room would aid the discolouration. Mr. Gulliver's method of painting backgrounds is on p. 165, No. 135.

Teesdale.—Your paper is unquestionably at fault; there is no remedy but trying another sample. 2. It is quite possible that your collodion is at fault, and not your bath, but from your description the lines and stains appear to be caused by the draining of the silver running back on to the plate during development. On removing a plate from the nitrate bath let it first drain a minute or two into the bath; then carefully wipe the back with blotting paper, and let the plate rest a minute on blotting paper to remove all excess of silver. 3. The prints are very good. "The Dairy Bridge" is best. The "Abbey Bridge" just lacks a little brilliancy. The "Railway Bridge" will be doubtless a very good subject for the stereoscope, but of its stereoscopic effect we can say nothing, as you only send one half. It has the least pictorial value. The scenes are all familiar to us, and very interesting from early association.

A would-be Photographer.—If you send us your address we can give you the information you desire. A very fair half-plate equipment for commencement can be had for £10.

J. G. D.—In making a silver bath for negatives dissolve 35 grains of re-crystallized nitrate of silver, in each ounce of distilled water. Immerse a coated plate in it for an hour or two, and then proceed to try a picture. If the silver have been pure and good, you will probably get good results. We have frequently done so. If not, add a little oxide of silver, let the bath stand in the light a few hours, filter, and then add either a little acetic acid, or nitric acid; if the latter, in infinitesimal doses. 2. The chloride of silver precipitated from silver solutions is easily removed by decanting away the supernatant water.

J. H. and some other Correspondents.—We have no personal connection with advertisements which appear in our columns, and specimens or other things left at our office, are there for the convenience of advertisers and those readers who may desire to call and inspect. We cannot undertake to give opinions or descriptions of articles so advertised. The camera in question was, we understand, sold a week ago.

N.—We are not aware whether it is absolutely known what is the dessicating agent used in Marion's preservative case, but believe it is generally understood to be chloride of calcium. One grave error in the construction of the case, is the absence of any facility for taking out the chloride and drying or replacing it. As it only acts in virtue of its power of absorbing moisture, it must be constantly deteriorating both from water absorbed from paper placed in it, and from the atmosphere, and thus eventually become charged with water. It would appear that in this case the chloride having become supersaturated with moisture, deliquesces, and runs off as described. Chlorine would of course discharge much of the colour of blotting paper stained with nitrate of silver. The only remedy will be to take the case partly to pieces and renew the chloride. We shall be glad to hear from you on the subject named.

F. M.—Do not add nitric acid to an iron developing solution for negatives. Acetic acid or citric acid should be used. The latter keeps the shadows clearer.

R. H. C.—We have some important information to communicate on the subject in our next.

M. H.—A portion only of the article has appeared. We will give a *résumé* containing all that is important, as soon as it appears complete. See article in present number.

W. G.—The particulars of M. Joubert's process have appeared in our columns, and our correspondent can compare his own method therewith and ascertain how far it is likely to infringe M. Joubert's patent. We believe M. Poitevin's perchloride of iron process is not patented in this country. Our correspondent can procure M. Joubert's specification from the Patent Office.

L. and several other Correspondents in our next.

Mr. Sandfords' and several other advertisements are compelled to stand over until next week for want of space.

D. Hills.—We have a letter for this correspondent if he will forward his address.

Mcs.—In our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 145.—June 14, 1861.

GALLIC ACID AS A PRESERVATIVE.

The value of a solution of gallic acid as a preservative in connection with several of the dry processes as suggested by Major Russell aud Dr. Ryley, has already been proved. It was illustrated to us in a striking manner the other day by Mr. Morley, who has been in the habit of using it as suggested by Dr. Ryley. Having prepared some ten-by-eight plates by the Fothergill process, using dilute albumen only, without either ammonia, chloride of any kind, or any organic salt, washing well before and after applying the albumen, they were dried and put away ready for use. On examining them, however, in the dark room, prior to exposure, it was found that they were much stained, and altogether unsatisfactory-looking, apparently from the use of badly-cleaned plates. It occurred to Mr. Morley, from what he had observed of the action of gallic acid, to try an application of it to these plates. One was taken as a trial, and the gallic acid solution poured over half of it, left to dry, and then exposed and developed. The result was most remarkable. That part of the plate which had not been treated with the gallic acid, was not only stained, from the plate being dirty, but the image was feeble, muddy, indistinct, and worthless. That part coated with gallic acid, up to every edge marked by its irregular flow, presented a clear, rich, brilliant, vigorous image; full of detail and crisp definition. Stains of every kind which might have existed in the film, seemed quite ignored, and that half of the plate had as perfect a negative image as could be desired. The exposure was four minutes, in a moderate light towards evening, with a lens of thirteen or fourteen inches focus, and a small stop.

One or two persons to whom we have mentioned this this method, and who were in the midst of some fogging difficulties with their Fothergill plates, have tried this remedy with the most complete success. We commend it to the attention of any of our readers, in similar difficulties, and shall be glad to hear of the issue.

BIRMINGHAM PHOTOGRAPHIC EXHIBITION.

It is we believe five years since an exhibition was held iu connection with the Birmingham Photographic Society, and the result on that occasion was a pecuniary loss. Notwithstandiug a discouragement of this nature, with that courage and enterprize which has placed Birmingham as one of the first manufacturing towns in the world, the society resolved to illustrate once more the progress of photography, by establishing another exhibition. On this occasion we are happy to believe the arrangements are such as will preclude the possibility of any very heavy pecuniary liability either by the society or its officers.

The exhibition is now held at Astou Hall, a place which, if it have the disadvantage of being a few miles out of the town, possesses also its own attractions of positiou, scenery, association, and the vast interest of its collection of curiosities in nature and art. Aston Hall, as some of our readers may be aware, is a fine old Elizabethan mansion, situated in a noble park a short distance from Birmingham. Possessed of many interesting historic associations, not the least of which is the fact that it once gave shelter to the ill-fated monarch Charles I; it has passed through many fortunes until, in the year 1857, a company was formed by gentlemen interested in preserving to the town the advantages of a park, aud place of amusement, who purchased the Hall and as much of the park as remained intact. The interior is converted into a museum of natural and artificial curiosities with which it is in many respects well furnished, and was inaugurated by Her Majesty in 1858. It is in some of the rooms of this ancient building, and forming for the time one of the features of attraction of the place, that the photographic exhibition is opened.

In using the term opened we are scarcely strictly correct. From the tardiness with which contributions were at first forwarded, the arrangement and cataloguing were unavoidably delayed, and we regret that in our necessarily short visit we were unable to see the display in that state of completeness which it promised in a few days to assume.

The pictures contributed at the time we were present, numbered upwards of 360, and more were promised. Of these, many we had already seen at the London Exhibition, but there were amply sufficient novelties to give the exhibitiou a distinctive character and individualism of its own, and render it well worthy of a visit. Foremost amongst these characteristics are the stereoscopic transparencies of Mr. Breese, a member of the Birmingham society. Of these pictures we shall speak more in detail next week; but we may here remark that they far surpass in wonder and beauty anything of the kind we have seen. We do not simply refer to the interesting instantaneous pictures, representing the streets of Birmingham during Her Majesty's visit to inaugurate the hall of which we have spoken, the views of which elicited Her Majesty's high commendation, but to the wonderful representations of clouds, water, and atmosphere, rising and settiug suns, and, most marvellous, moonlit scenes. A series of pictures from China, the display of solar camera pictures, and some other excellent pictures all coutribute to give the distinctive character to which we have referred.

More immediately associated with the department of the Hall devoted to Chinese illustratious, but as possessing high photographic interest, we may first mention the photographs from Chiua, contributed by Philip Cohen, Esq. Amongst these are photographs of the summer palace of the Emperor, which was sacked in the war, and of various scenes in connection with the war. Some of them possess a horrible and ghastly interest: scenes immediately after the couflict, in which the bodies of the slaughtered Chinese are scattered around, and in some cases blood trickling from their wounds, all of which is rendered with a sickeuing fidelity. A panorama of Pekin is upwards of six feet long. The pictures, although somewhat marred by spots and pinholes in the negatives, apparently from dust, are full of detail, and in many respects very good photography. We have uo information as to the artist, but are disposed to attribute them to Signor Beato, who, it may be remembered, was described by the *Times* Chinese correspondent as being present with the army at the time.

First in position in the catalogue, and in many respects taking priority in interest, as being the first time they have been invited to a formal competition for medals, stand the solar camera pictures. Of these there are about twenty-one: four contributed by Augel of Exeter; six by Smyth and Blauchard of London; three by Atkinson of Liverpool; five by Turner of Birmingham; and three by Pickering, of Birmingham. Four of these are coloured, and one worked up iu black and white. Amongst the coloured ones a very large portrait of the late Rev. J. Angel James of Birmingham, by Mr. Turner, will attract most attention. The size of the picture is 44 in. by 34 iu. The position and expressiou are easy, natural, aud characteristic. The painting is good and the effect throughout such as will, we apprehend, leave little ground for hesitation in the judges regarding the best coloured picture. The uncoloured duplicate is present for reference, but is not hung. It is on a sheet of double elephant drawing paper, a few inches each way less than the painted copy. The likeness in it is good, but the print is a waste copy, stained and imperfect. The high esteem in which the deceased minister was held in Birmingham must give a peculiar interest to such a life-like representation of him. Mr. Turner's uncoloured pictures do not please us so well. He uses, apparently, negatives sufficiently dense for ordinary printing purposes; and hardness, mistaken for great vigour, is the consequence. His prints are developed too long, and acquire a greenish tone.

Mr. Angel, of Exeter, exhibits four very fine prints, which at the distance from the eye at which they are hung leave nothing to be desired, unless it be a little more warmth in tone. Two of his prints are groups of full-length figures, on whole sheets of photographic paper rather closely trimmed. One, a charming picture of two young ladies in walking costume. The drapery in this picture is very exquisite, and if there were a little more modelling in the face it would be perfect. Another is a group of four children, well posed, and satisfactory in general character. Two others are busts a little less than half the size of life, which present some sharp, vigourous, and clean photography. The whole of Mr. Angel's prints appear to be on albumenized paper, sun printed and toned with gold, in contradistinction to the others, which are developed prints on plain paper.

Smyth and Blanchard contribute six, all on the ordinary whole sheets of photographic paper. These are very unequal in merit, three or four are very good, one indifferent, and one very bad, being hard, flat, and unpleasant in tone. Two large vignette heads are very good, and two large heads not vignetted are also good, but the other, with more of the figure, will not compare with those of the same kind of Mr. Angel. The best of these, and those of Mr. Angel, will run very closely in competition: the latter are more delicate, and the former more bold in treatment. Those of Smyth and Blanchard are all developed prints, and the tones of the best as fine as can be desired. Some of these prints present a very slovenly appearance, being sent without frame or glass; and the mounting boards warping, spoil the effect materially. Such a practice cannot be too strongly deprecated.

The three large vignette heads, sent by Mr. Atkinson, strike us as being very unsatisfactory. Two of them are very flat, and the third, although possessing a little more modelling and somewhat bold, is still hard and crude. Of Mr. Pickering's enlarged pictures, two are coloured, and one worked up in black and white, and do not present much ground for photographic comment.

We believe there are four solar cameras in Birmingham; but only two of the artists of the town have at present contributed enlarged pictures. We are somewhat surprised to see so few of the names of the Birmingham artists amongst the contributors; the more so as in our walks through the streets we were struck with the large number of show cases belonging to professional photographers, in many of which some excellent specimens were exhibited. Perhaps their contributions have yet to be sent in, and the thing which from its easiness may be done any day, is being delayed, as is the too prevalent wont of human nature under such circumstances.

Among the general contributions are, as we have said, a number of old favourites, in both landscape, portraiture, and *genre* subjects, together with new ones which ought to become favourites. Here is a fine display of Bedford, and Mudd, and Heath, and Rejlander, and Robinson, and Claudet, and Wall, and a 'host' of others. There are immense pictures from waxed paper negatives by Rogerson of Manchester, views from the Crimea and Constantinople by Robertson, and from Corfu by Major Shakspeare. We must, however, enter into further detail in another notice.

Notes and Jottings.

No. 7.

Suggestive Experiments on the Resin Dry Process—Keeping Qualities of the Albumen Solution, and of Prepared Plates in Modification of the Fothergill Process.

The resin process for dry plate photography, if it could be relied on, would assuredly be the most simple.

Considering the very minute quantity of resin recommended to be added to collodion, it appeared to us probable that a small portion of benzole or naptha would answer the same purpose, and work cleaner. The benzole or naptha should be somewhat impure, so that on a portion being evaporated, a resinous matter may remain. Parrafin, "or other similar substance" may be employed in like manner.

The few experiments we have made in this direction, give sufficient promise to induce us to continue them at an early opportunity. The plates were very sensitive, requiring not one-half the exposure of those by the Fothergill process.

Instead of adding the resinous oil to the collodion, it may be largely diluted with water and applied to the washed sensitized plate as a preservative. The film should be thoroughly washed and drained, and the solution, after having been allowed to stand for some minutes, washed off. We cannot with certainty give the best proportions in which the above mixtures should be made. Perhaps from 5 to 10 minims of benzole, &c., to the ounce of collodion, or twice that quantity to the ounce of water, will be found to answer.

The film, however, by either of these methods is not so compact as could be desired, and unless the last washing be thoroughly effected, stains will arise.

We think it probable that resin, or resinous oils, either mixed with collodion, or applied as a preservative, will be found to give a more sensitive dry process than any other yet published.

Some doubt has been expressed as to the length of time the mixture of silver with albumen, for the modification of the Fothergill process, will keep. We have lately used some over two months old as good as when first made.

A plate prepared six weeks before exposure, showed not the slightest sign of deterioration, and we consider that if the last washing has been effectively done, the plates by this process may be kept for any length of time.

Michael Hannaford.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.*

Grace.—One of the attributes of beauty, which invariably produces a pleasing effect. A portrait of the homeliest woman, if gracefully posed, will convey an impression of beauty to the spectator's mind. *Grace* may exist in a thousand ways, and in connection with a thousand things, and yet be equally effective in each. We find it, for instance, in animate and inanimate objects; in the arrangement of a single figure and the disposition of parts in a composition; in the expression of the face, the folds of drapery, and in the action of the body and limbs; in the droop of plume-like boughs, the sway of the green grass, and the grouping of forest trees: or in the contours of the noble horse, the gamboling grey-hound, the timid deer, the swan, and the bounding stag. *Grace* should always be sought by the artist photographer, whether his search be carried on in the wide out-of-doors studio, or the little blue-blinded glass room. Nature is lavish of it, to all whose minds have taught their eyes to see it, although night-blinded bats, whose eyes are nothing more than mere mechanical guides for their hands and feet, never recognizing either this or

* For *gamboling* in the quotation from Rejlander's paper under the head "Glazing," read *gambling*.

kindred qualities, refuse to seek, or even deny its existence. Jarves, an American writer on art, says—"Sublimity may be considered, for the present, as out of the power of art; except in a merely suggestive sense. *Grace*, however, is completely within its power. The artist who fails therein has no calling for art. *Grace* is everywhere. There is not a line of nature or created object, but, in some form or other, develops this quality. Therefore is the artist inexcusable who lacks its spirit." *Grace* varies in its character, for it may be homely and familiar, subtle and refined, or majestic and retiring. The gracefulness of motion has already been the subject of remark in these articles (see *Action*, *Attitude*, &c.), and the quality has been shown to be very closely allied thereto. Among things destructive of grace, the most common will be found to exist in a want of proper harmony, or keeping,* and in the presence of harsh contrasts and crude abruptly angular outlines; but the quality itself is hard to define, being so frequently felt without being understood, and clearly recognized without being traced to its source. I will not, therefore, dwell longer on this subject.

Grouping.—The great law of composition, viz., *Unity*, is also the chief element in artistic grouping. It is tolerably well known that, with this end in view, the best form of composition, in grouping, is the pyramidal; but it seems to be a fact very much less known, that, although such is the case, the pyramid should not be so arranged as at once to suggest the intention of the artist. When a group of figures assume this form, it should appear to result from the merest accident, and be perfectly natural and consistent. No one figure should have the appearance of being posed in a certain way *merely* to complete the pyramidal figure of the whole; but, while actually doing so, should suggest some other cause for its appearance more strikingly intelligible to the unprofessional spectator. In photographic groups of three, we frequently find them posed in the tit-tat-toe order, with two figures seated, one on either side of another standing: here it is true the pyramid has been secured, but what can be more formal, stiff, and ugly; or less suggestive of anything but three tasteless people sitting for a vulgar portrait to some lamentably pictorially ignorant operator. Art is deeper than the mere surface quality of common-place artifice; and a group is not artistic merely because the tallest figure stands in the middle. In a group also—and here lies a photographic difficulty which "composition" printing finds its best reasons in†—the figures should not be all "drawn up" exactly in one plane. The better arrangement, if the form of lenses would permit, would be that which makes the more central figures prominent, and those at the sides receding. It is almost impossible to lay down rules applicable to all cases, because such are liable to be influenced by so many other principles, more or less peculiar to different works. I shall, therefore, merely suggest that the forms into which groups are most frequently arranged are the pyramidal, dome shape, oval, circular, and spiral, as influenced by the laws of *Proportion*, *Balance*, &c., and above all, by *Expression*.

In landscape it is astonishing what capital foregrounds may sometimes be got by a little artistic grouping of the stray articles chance may place within reach. A large broken bough, dragged into a judiciously chosen position; a few large stones and weeds; a dilapidated wheelbarrow; a few farming implements; some old peat-baskets; a stray male or female, or male and female rustic; a horse or cow, hunted into the right position; a picturesque ferry-boat—all these, and many other things, when appropriate to the locality; and the sentiment of your view will compose into the most charming and effective foregrounds, with no other trouble—if you have the proper knowledge of pictorial effect—than that of a few thoughts, and a little careful observation. In grouping or massing these together, remember their effect in reference to the other laws of pictorial art, so as not to destroy the unity or repose of the *composition*; this last effect being the result of *subordination*. The use of such chance-found accessories, when grouped as described above, may also aid in securing breadth of chiaroscuro, or gradation of tones by supplying such half-tints as are required to unite two opposing masses. Much could be advantageously added on this subject, perhaps; but these papers having already extended over as much space as I originally intended they should occupy when complete, the reader must excuse me if I begin to be somewhat more purely and briefly explanatory in my treatment of the terms yet remaining.

Harmony.—The great sources of harmony are unity, repetition, and proportion. If you are about to print a picture containing many objects from a set of negatives taken at various times, be careful that there is such similarity of tone and gradation in each as may be consistent with the peculiar conditions of light, shade, &c., under which the whole is supposed to exist; otherwise, your picture will be out of harmony. In a properly harmonized picture one part, will be in perfect agreement with every other part; lights of the same character or kind will be of the same relative degree of brilliancy, and shades of the same relative degree of depth throughout, harsh isolated sections will not exist, and every part will blend and unite with every other part in tones, lines, and general disposition of parts. Considered away from "composition" printing, and, with reference to harmony of tones, I may remind you that the various parts of a picture must be regarded with the feeling due to a well-composed piece of music, in which one particular key rules the whole. Upon the exposure, development, and printing combined, this quality must be dependent so far as regards the proper *harmony of tones*; but beyond this we have also to consider the *harmony of expression*, *harmony of proportion*, and *harmony of effects*. I cannot hope to make you thoroughly understand this quality, it being so much more a thing for feeling than reasoning about; but seeing the harmony of a good picture should engender in you the same sensations that would arise from hearing the harmony of good music. The two things are essentially the same.* In one of Ruskin's works—I forget exactly which—he speaks of this quality as being to a large extent too subtle for definition; and I am therefore sure you will not expect more from Wall the pigmy, than you can get from Ruskin the giant. To illustrate harmony of expression, however, we will, if you please, appeal to our imaginations.

The sun has gone down beyond the distant hills, which rise, ghost-like, against the pale gleaming light of the western horizon. A misty gloom spreads over the whole scene, and the dark forms of the distant trees, with their rounded heads and drooping boughs, defined against the pale greenish light above the hills, show like hooded mourners bending above the grave of departed day. The sad-voiced breeze sounds sigh-like. The mournful solemnity and mystery of night's approach shows everywhere; in the mystic depths of violaceous gray above, and in the thickening gloom which shrouds objects below. Among these objects, more distinctly visible, because nearer, a deserted plough rests in its half-formed furrow; and a dead lonely oak spreads the angular abruptness of its gnarled and twisted boughs, black against the darkening sky. A thin white face, a shrunken form, clothed in dirty rags, and prostrate, shows where a starving vagrant has crept to breathe his last.

The coming night, the mourners on the hills, the wind-breathed sighs, the plough, speaking of work done, and work

* "That grace and propriety are inseparably united, may be demonstrated from the different languages of both ancient and modern times, in which the words *proper* or *becoming* are, in many cases, synonymous with *beautiful* or *graceful*, and may often be used indifferently the one for the other."—*Cabinet of the Arts.*

† The solar camera may relieve us of this difficulty, and rob the "composition" printers of this excuse, perhaps, by enabling us to get our groups on small plates, and then enlarge them to the required size. I am now preparing some groups for experiments in this direction, taking them with some small Dallmeyer lenses admirably adapted to such purpose.

* I am no musician, or I might probably find, and render you help through a better knowledge of the laws regulating harmony, or thorough bass.

deserted; the lone, dead oak; the thickening gloom, and the mystery which shrouds retiring objects; these whisper silently to our awe-struck souls; but they all whisper of *one subject only*, of that lone deserted vagrant there, with the mists of death, and the darkness of a mysterious night stealing down over his tear-damp couch, in the hushed and solemn silence of the deepening twilight. The dirge has its mournful cadence everywhere; but more than all in our own souls, so that the very beating of our heart almost grows noisy, and to speak aloud seems sacrilege. The sad and eloquent power of *harmony* steals into our full hearts, and gives the tone of our pensive thoughts. If you can imagine some such illustrative picture, (many such have been painted) and conjure up the feelings it would engender, you will have a better understanding of the meaning embodied in the terms, *harmony of expression*, than I could convey by a more common-place method, or by dwelling at greater length on the subject.

Heterogeneous.—Confused, without order; caused by associations out of harmony, or contradictory in their nature, or objects false and out of place in their positions.

High-art.—Frequently confounded with big art, and commonly associated rather with quantity than with quality. A thing more talked of, and loudly, although less understood, than lower art. Too high for the reach of cameramen, but quite as far from the touch of nearly all the best of our modern masters in painting.

Scientific Gossip.

The members of the Royal Institution were gratified on Friday evening last (the concluding meeting of the season) with an experimental illustration of the recent spectrum discoveries. The lecture was by Dr. Tyndall, and was on the *Physical Basis of Solar Chemistry.* He commenced by referring to certain memoranda connected with the absorptive and radiating power possessed by gases on the rays of heat, and then proceeded to illustrate these experimentally. The first was that gases radiate heat in different degrees, some radiating scarcely any, whilst others radiate it in quantity. To render this evident, a thermo-electric pile was placed in connection with a delicate galvanometer. The pile was so arranged that an exactly equal amount of heat impinged upon each end, being radiated from square boxes filled with boiling water; the one face having near it a hot copper ball, resting upon a ring gas-burner (not lighted). The gas-burner was placed by an appropriate arrangement of tubes and taps, in connection with gas-holders of oxygen and of olefiant gas, so that either of these gases could be sent through the ring burner, and passing roundthe hot copper ball would rise up round it in the form of a sheet of heated gas. The arrangement having been explained to the audience, the experiment was performed:—the copper ball was properly placed; the needle of the galvanometer was brought to zero by appropriately adjusting the sources of heat at each end of the thermo-electric pile, and the oxygen was then allowed to flow through the tubes. It passed over the copper ball, rose from it in a highly heated state, and then proceeded upwards in front of the face of the pile. If the oxygen were capable of radiating heat in a sensible degree, it would at once have been rendered evident by a movement of the needle of the galvanometer; no such motion was, however, perceptible; oxygen gas, therefore, radiates no appreciable amount of heat. The same experiment was then tried with the substitution of olefiant gas for the oxygen. A great difference was at once observed between these two gases. No sooner had the warm olefiant gas risen in front of the face of the pile than the needle of the galvanometer showed that heat was being radiated from the gas in large quantities; it was instantly deflected, and in a few seconds had swung round 90 degrees.

The fact that gases radiate heat in different degrees having thus been shown experimentally, the lecturer proceeded to illustrate the different absorptive powers which they possessed. A similar arrangement to the above was employed, only the copper ball was dispensed with, and the gas was allowed to issue through a narrow slit in the front of one of the sources of heat, whence it rose in the form of a thin wall of gas, between the heat and the face of the pile. As before, the oxygen produced no effect upon the galvanometer; it allowed the heat to pass through without absorbing an appreciable quantity, forming in this respect a marked contrast to the olefiant gas, which under the same circumstances obstructed a great quantity, deflecting the needle as much as it had in the former instance.

It was thus shown that gases which radiated little, absorbed little, whilst those which absorbed much radiated much; the proportion between their absorptive and radiative powers being always constant.

The lecturer next proceeded to show that gases did not absorb rays of heat (or light) uniformly: they seemed to exhibit a marked antipathy to certain rays, seizing hold of them, and killing them, whilst other rays on each side were allowed to pass untouched. This was shown in a striking manner in the case of nitrous acid, a cylinder of this gas, interposed in the path of a ray of electric light, which was afterwards passed through an arrangement of prisms and lenses to form a spectrum on a screen, being seen to cut up the colours into alternate light and dark bands, showing that it exercised a kind of preferential action upon some rays of light, absorbing these whilst it allowed others to pass. The converse of this was next shown. Nitrous gas having the property of absorbing rays of light in different parts of the spectrum, other gases had the property of emitting certain definite coloured rays. To show this, metallic vapours were chosen, the phenomena being seen in the most striking manner with these bodies. Retaining the same arrangement for producing an electric spectrum as was used in the case of nitrous acid, the electric light was taken between mercury poles. Instantly a few isolated bands of brilliant colours—red, orange, green and blue—were seen, instead of the continuous spectrum previously given by the carbon poles. The mercury was removed, and poles of brass substituted. These gave the brilliant compound spectrum of the zinc and copper, and the lines due to each element were pointed out, it being at the same time explained that these lines were always constant for the same metal. Whenever the smallest trace of the element was present under these circumstances the lines were produced, and conversely whenever a person acquainted with the different appearances of these lines saw any of the systems, he was as absolutely certain that they were evidence of the existence of the particular metal as if he had the metal itself in his hand; just in the same way as the audience might be equally certain that he was then speaking to them, whether they heard him from a distance or he were whispering into the ears of each individual.

The next spectrum which was shown was the beautiful one produced by strontium (which, however, by a slip of the tongue, the lecturer persisted in calling lithium all the time). This was produced by boring several holes in the ends of the carbon poles, and plugging them up with a compound of the metal—the chloride of strontium for instance. Upon making contact with the battery, the brilliant lines due to this element became projected on the screen, and attention was particularly drawn to the magnificent blue band which was produced in this manner. Sodium was next tried, and the brilliant double line which this produced in the yellow part of the spectrum was exhibited in a very beautiful manner. The spectrum of this metal, although not so beautiful in colour as some of the preceding, is well worthy of attention on several points. It is exactly identical in position and appearance with the line D in the solar spectrum, and this fact first led philosophers to suspect that there was a connection between the two. This has now been proved in the following way:—It was shown that, from theoretical reasoning, a gas which when luminous would emit a ray of a certain refrangibility, would also absorb the same ray if placed before its path. The incandescent vapour of sodium, therefore, which emitted a ray of a certain definite refrangibility, should, according to this reasoning, be opaque to the same kind of ray. To show that this was the case, a very pure spectrum of the electric light was thrown upon the screen, and the position occupied by the soda line in it pointed out. In the path of the light was then interposed a large flame of alcohol and water, in which some chloride of sodium was dissolved; this gave an intensely yellow flame, which was seen to be opaque to the yellow line by causing a black mark to shoot across the spectrum in the position formerly occupied by the luminous line. This was shown in a more striking manner by burning a piece of metallic sodium in a gas flame, in front of the slit of the spectrum apparatus; a jet black line was at once seen to shoot across the spectrum, producing artificially Fraunhofer's fixed line D of the solar spectrum.

The presence of the dark line D in the spectrum of the sun, was therefore shown to be a conclusive evidence of the presence of the metal sodium in that luminary, and in the same manner it was rendered equally certain that the sun likewise contained iron, magnesium, and other metals in its atmosphere. These metals were all necessarily in a gaseous state, and the fixed lines in the solar spectrum were caused by the more highly luminous body of the sun shining through the metallic vapours which formed its atmosphere.

WAY'S ELECTRIC LIGHT FOR PHOTOGRAPHIC PURPOSES.*

It is not necessary that I should offer to you, sir, or this meeting, any apology for the subject I am about to bring under your notice: for the possibility of making the electric light subservient to our purposes in photography, is too important and too interesting to need my excuses.

I cannot, though, commence the observations and explanations I have to make, without asking you to join me in expressing our acknowledgments to Professor Way for giving us this opportunity of witnessing the results I propose to show you.

Most of us are aware that the electric light has not only been proposed, but used, for photographic purposes. At the commencement of our present session, Mr. Malone read a paper in which he stated his experiences with a Duboscq lamp. A somewhat similar lamp has been used in Paris for both portraiture and printing, and I believe at this moment, in this country, Mr. Silvy is using the electric light for enlarging.

The peculiarity of Professor Way's light is in substituting a continuous stream of mercury for the ordinary charcoal points.

The Duboscq lamp, and other modifications of it, Mr. Crookes describes in the Photographic News, as "consisting of a pair of charcoal points separated from each other by a small fraction of an inch, and being connected with the opposite poles of a powerful voltaic battery. The interruption caused to the passage of the electricity produces a brilliant evolution of light and heat, where the electricity bridges over the interval. So far there is no difficulty; but the carbon poles are constantly wearing away, and the space between them thus becoming larger, soon presents a barrier to the further passage of the current, and puts out the light. In order to avoid this inconvenience, many automatic lamps have been devised, in which by the aid of clockwork, electromagnetism, &c., the poles were kept at the proper distance apart."

Professor Way's plan is, as I said this moment, to use in lieu of the charcoal points, a fine stream of mercury, which is made to fall from a jet into a cup. The description and explanation of the lamp is this:—It will be seen that it consists of two parts—the reservoir or cistern for the supply of mercury, and the lamp itself.

* Read at the Meeting of the London Photographic Society on Tuesday June 4th.

The former comprises suitable bearings, carrying two hollow arms, at the ends of which are two globes containing mercury. Either of these globes may be brought uppermost by the rotation of the arms upon an axis placed at their point of junction. The two globes communicate by means of the hollow arms, having holes drilled near the axis with two nozzles on the front of the apparatus; from these nozzles, tubes convey the mercury to and from the lamp.

When the upper globe has discharged all its contents through the lamp into the lower globe, the arms are turned half round upon their axis; the emptied globe being thus brought to the lower position, and the full globe brought to the upper position, by which contrivance a constant stream of mercury is obtained. A gauge tube indicates the pressure of mercury on a suitable scale.

The lamp itself is remarkably simple. The mercury as it comes from the reservoir is conveyed by a tube to a jet, and passes in a fine stream into a cup, and thence, by a second tube, back to the lower globe of the reservoir.

The length of this stream of mercury is adjusted by a rack and pinion, according to the size of the jet and battery power employed. A glass cover encloses the jet and its accessories, and confines the volatilized mercury. The positive pole of a voltaic series is connected with the jet, and the negative pole with the cup.

By the passing of the voltaic current between the jet and the cup, the mercury becomes intensely heated, and the light is produced.

"The light of this lamp differs," says Mr. Crookes, "in character from that produced from charcoal points, and from the lime light, principally in its great volume, appearing not as a single vivid point, but as a focus of considerable dimensions."

To photographers, the striking peculiarity and advantage of this light is, it possesses in a much greater degree than the electric light produced by ordinary means an intensely actinic character. The way in which it modifies the apparent colours of surrounding objects is very singular.

Whether among the important duties it may one day perform for photographers, the taking of portraits is to be one, I know not, but I venture to say, the intending sitter will not think the peculiar hues it imparts by any means flattering to personal appearances. [The gas in the room was here turned down to allow the peculiar effect of the electric light to be illustrated.]

Flowers, dyed wools, &c., are generally altered in colour. Photographers will appreciate the singular modifications effected upon colours when I point out to them that viewed by it the crystals of protosulphate of iron appear absolutely colourless. [The crystals were exhibited, looking rather like hyposulphite of soda than protosulphate of iron.]

Dr. Gladstone says, the prismatic analysis of this light explains at once the various chromatic phenomena. The brilliancy of the yellow, blue, and violet rays accounts for the beautiful colour of those objects which can reflect these rays; while the feebleness of the red shows the reason of the great changes which red substances invariably undergo—sometimes changing nearly to brown, at other times to purple, green, or whatever other colour in addition to red is principally reflected by them. Thus the blood, wherever it shows through the skin, as in the lips, appears of a bluish purple, instead of a reddish hue; and this explains also why sulphate of iron becomes perfectly colourless; for the ordinary green tint of this salt is due solely to its not transmitting with any freedom the red rays; it transmits all others, and therefore all those which prevail in the mercury light. Hence it appears of the same colour as the source of illumination itself, which the eye ordinarily recognizes as white, though, as compared with the sun, it is decidedly coloured.

[Mr. Heath, at this point, placed a piece of sensitized paper upon an easel opposite the Way's light, upon the same horizontal plane as the light, and exposed it for four minutes, and then placed another piece of sensitized paper for four minutes (both pieces being parts of the same sheet) opposite a Duboscq lamp, which Dr. Faraday had lent to Mr. Heath; but to some gentlemen in the theatre, they appeared to be in different relative positions, the last paper being apparently somewhat above the horizontal plane of the Duboscq's lamp. and at a somewhat greater distance than the paper exposed to the Way's light. Upon the two papers being developed and handed round, it was found that the one exposed to the Way's light was much more sensibly coloured than the other. See our report of the meeting.]

It will be remembered that in our late exhibition Mr. Bedford exhibited a frame of photographs which were printed, as a first experiment, with Mr. Way's lamp; and it will also be remembered that these peculiar photographs had all those brilliant, vigorous, and rich qualities for which Mr. Bedford's photographs are famous. One remark Mr. Bedford made as to his results with this lamp I am quite able to confirm—viz., that the light possesses a a singularly penetrating power. For this reason the negashould be somewhat dense, and probably it will result that a paper with less silver than ordinary in its preparation could be used. That is, if, as I believe, the lamp will come into use for printing purposes, we shall have to manipulate our negatives accordingly. An ordinary iron developed negative, which will by diffused daylight yield a most satisfactory print, will not be sufficiently intense to produce a brilliant print by this lamp.

Well, this result obtained in four minutes will demonstrate its penetrating and printing powers. It remains now, upon this branch of the subject, to say something as to the cost of working. The cost of the battery power is 2s. per hour, but what is most needed is to determine the best mode of utilizing the light. At two feet away from the light, I calculate twenty frames may be suspended and by the introduction of reflectors probably more.

Here, therefore, are the facts as they now stand, and upon which present experiments may be based; but as in everything else we must look to future experiments for the real development of its capabilities.

But in another direction, and one too in which the eyes of most of us are now directed (viz., that of enlarging), I think it is capable of affording great help.

I need not explain the drawbacks of the arrangement known as the solar camera. Those who can associate in their practice such a camera with the sunless summer last year, will appreciate some of its difficulties.

But for the Way's light, all that is required is a good magic-lantern arrangement.

I will endeavour to show this, and try to produce a result which shall have sufficiently that is promising about it, to justify my mentioning it.

Mr. Hughes has been good enough to volunteer most important help, by supplying me with a suitable negative and paper, and will undertake the development of the result the light will give us. [See the report.]

TRANSPARENCIES FOR THE STEREOSCOPE.

BY MR. LAWS.*

The subject upon which I have ventured to engage a small portion of your time this evening, is one requiring some person more practised in this particular branch of photography than myself to deal justly with. I have merely done a few transparencies, more as a change from the usual routine of portraiture, therefore I hope you will excuse any shortcomings. I think you will allow that transparencies upon glass, are much finer in the stereoscope than those printed upon paper. Beautiful as Mr. Wilson's stereographs are, how much more beautiful would they be upon glass.

I think one reason why photographers possessing valuable negatives, do not avail themselves of this beautiful process, is, that it gives such facility for unprincipled people to copy. Nothing is easier than producing a good negative from a good transparent positive, in fact the copy is almost, if not quite as good, as the original; in some cases a good printing negative can be got from a very weak one, by first taking a transparent positive, and then a negative from that again; you can get any amount of density in that way. I am much surprised at the amateurs, who, I believe, generally take more stereoscopic views than anything else, not working upon glass, it is a much more pleasant operation than paper printing, and the results are much finer. There are many methods of producing transparencies: printing in contact upon dry plates, is, I believe, most generally employed, there is, however, in my opinion, many objections to that plan; in the first place you must cut your negative in two and remove each half before printing in order to make it correct for the stereoscope, and again two hard substances like collodionized glass screwed closely together in a printing frame, must be attended with great risk to the negative.

Mr. Negretti, in a conversation at the Blackheath Photographic Society, states that he had some negative collodionized plates, which had received three coats of varnish, and yet he never could take a print from them without making holes in the negative. Soulier and Ferrier also print by super-position, but they work entirely upon albumenized plates, so the risk of damaging the negative is less, but still they *are* often damaged. When Soulier's negatives become injured by use, he repairs the proof by retouching in indian ink, he (Negretti) had seen nearly a whole tree put in in a most exquisite manner; now we are not all such artists upon glass as Soulier, for however beautifully damages can be rectified, it still takes from photography something of its truthfulness; therefore, to any of you who wish to produce transparencies, either for the stereoscope or magic lantern, I can recommend the plan I have adopted as being both simple easy, and without the slightest risk to the negative. It is by no means new; my attention was first drawn to it from an article of Mr. Sutton's in the *Notes* some time ago.

The camera I use consists of a long dark box, with a partition from end to end; in the centre I place two ¼-plate lenses, at the extreme end I have a groove for receiving the negatives, at the other end I insert my prepared plate. I fix the camera upon a stand, and point it towards the sky (northern is best); by using very small stops a transparency can be got quite equal to the negative in sharpness. I should have stated that the camera is made in two portions, one sliding within the other. Having placed the lenses at the proper distance from the negative, which entirely depends upon the length of focus of the lenses, I get the image perfectly sharp upon the ground glass by sliding the camera in or out. When no more focussing is required, I then prepare a plate in the same manner as for a negative, by the usual wet process and exposure in the camera; the exposure depends, of course, upon the light and the density of the negative. Negatives full of detail and with very little density give the best proofs. I develop with pyrogallic acid, acidify with citric acid in the usual quantities. When everything is in good working order, fine rich blacks can be obtained without adding any silver to the developer, which ought always to be avoided as much as possible. By placing the negative upside down, with the film outwards, the transparency is taken correct for the stereoscope without cutting the negative. The camera I have described can only be used for negatives taken with the lenses 2½ inches apart; when they are separated more than that, they must be copied with one lens in a camera with the slide made to shift, so that only one half the plate is exposed at once; in a good light there is no inconvenience in this plan, but when the light is bad it is very awkward, the last half of the plate requiring more exposure than the first; the specimens I have brought are backed with opal glass, which I like very much, but it is rather more expensive than ground glass. I think if each of us were to print some transparencies from our negatives, we could spend a very interesting evening next

* Read at the meeting of the Newcastle Photographic Society on the 7th inst.

winter, by having them shown by means of the oxyhydrogen light; but it is rather out of place speaking of winter now with the summer before us, which I hope will show more favour to us photographers than the last.

THE PHOTOGRAPHIC SOCIETY AND THE INTERNATIONAL EXHIBITION OF 1862.

The following is a continuation of the correspondence between the Chief Baron, President of the London Photographic Society, and Her Majesty's Commissioners for the International Exhibition of 1862, regarding the position to be occupied by photographs on that occasion. Our readers will remember the Chief Baron's letter published in our number for May 17. The answer of the Commissioners here follows, together with the further correspondence which has arisen.

Offices, West Strand, London, W.C., May 16, 1861.

Sir,—I am directed by Her Majesty's Commissioners to acknowledge the receipt of your letter of the 7th instant, to which they have given their most careful consideration.

The views of the Council of the Photographic Society seem to be based on a misapprehension of the intention of the decisions published by the Commissioners, as there is nothing in those decisions which would imply that Photography may not be placed either in a separate room or in juxtaposition with engravings, or any other analogous and suitable class of objects.

It is the wish of the Commissioners to do the utmost honour to the exhibition of Photography, and the scientific instruments essential to the practice of that art. With this object they, have removed it from the subordinate position which it occupied in 1851, and have constituted it a separate Class, to which special space will be allotted.

They hope to induce all the exhibitors in this Class to assemble together in one apartment all their Photographic Apparatus and Photography, so as to illustrate fully the state of Photography as practised throughout the world at the present time.

Her Majesty's Commissioners entertain no doubt that this explanation will be sufficient to secure the valuable co-operation of the Council of your Society in the forthcoming Exhibition, as requested in my letter of the 26th ult.—I have the honour to be, sir, your obedient servant,

F. R. Sandford, *Secretary.*

The Rt. Hon. Sir F. Pollock.

Court of Exchequer, Westminster, May 24, 1861.

Sir,—The Council of the Photographic Society have been assembled, and have had laid before them the letter which I have had the honour of receiving from Her Majesty's Commissioners through you.

The Council is most anxious to concur in whatever may promote the success of the Exhibition, either by assisting in the appointment of a Committee, or in affording the most zealous co-operation; but they do most earnestly hope that their claims will be admitted, and their request be complied with—viz., that their apparatus may not be exhibited in the same room with the results which arise from the use of them.

As a science, Photography, like every other science, is incapable of being exhibited. But when embodied in the artistic results with which every one is more or less familiar, Photography, as an art, is capable of contributing to an exhibition matters of the greatest and most universal interest, embracing every variety of object which can gratify curiosity and afford pleasure. It would be most painful to the Council to have, blended with these results, the mere apparatus which they use as tools: neither could throw any light upon the other; and I am desired by the Council to press this upon Her Majesty's Commissioners, and to solicit an interview, when the Council will, by a deputation, wait upon the Commissioners, and explain more at large the views they entertain on the subject.—I have the honour to remain your obedient servant,

Frederick Pollock.

454, *West Strand, London, W.C., May* 29, 1861.

Sir.—I have submitted your letter of the 24th inst. to Her Majesty's Commissioners, and am desired to express their gratification at receiving from you an assurance of the readiness of the Council of the Photographic Society to co-operate with the Commissioners in carrying out the undertaking which has been entrusted to their management.

They will be glad to learn, at an early date, the names of the gentlemen whom your Council would recommend for appointment as a Committee in connection with Class XIV.

Any suggestion which this Committee may make with respect to the position to be assigned to the various objects that they may consider entitled to admission to the Exhibition, will receive the most careful consideration of Her Majesty's Commissioners, when they proceed to the ultimate distribution of space in the building, and to the arrangements connected therewith; but they feel that it would be premature, at this time, to discuss any of the questions connected with this part of their duties; and so many other matters are at present occupying their attention, that they regret their inability to receive the proposed deputation from your Council.—I have the honour to be, Sir, your obedient servant,

F. R. Sandford, *Secretary.*

The Right Hon. Sir Fred. Pollock.

The following is the letter of Professor Playfair referred to in our last.

University of Edinburgh, May 27th, 1861.

Sir,—At the request of one of the Members of your Council, I write to you on the position given to Photography in the classification of the Exhibition of 1862. My apology for doing so is, that I was the responsible officer for framing the classification adopted in the Exhibition of 1851, upon which that of 1862 is founded; and further, that as a Member of the Committee of Organization, the present classification has been brought under my notice by the Commissioners.

You have no doubt observed that the general principle of the classification is to group the raw materials employed in industry, then to group the machinery used to convert them into utilities, and lastly, to group the utilities themselves as manufactured products.

The group Machinery cannot embrace Photography with any propriety. If it has been placed there on account of the apparatus employed in its production, this in itself is a misunderstanding of the principles upon which the classification was framed. Cameras belong to the general class of "Philosophical Instruments," and have no more title to a separate class in machinery than telescopes, microscopes, electrical or surveying instruments, all of which are sections of one class.

But the mixing-up of the photographic pictures with the instruments employed to produce them, when the art has developed in magnitude so as to entitle it to special exhibition, is a gross philosophical error. With equal ignorance, the works of the sculptor and engraver might have been appended to cutlery and edge-tools, or the works of painters to the classes which include brushes made from hair, or to chemical products.

But besides this philosophical error, which will deface the classification in the eyes of foreign nations, who have attended more to its principles than we have in England, the proposed arrangement will be inconvenient for the purposes of instruction, and for the consideration of the jurors who have to judge the works exhibited. The visitor to the Exhibition cannot benefi by the abrupt transition from machinery, in its varied forms, to photographic pictures; and the jurors on machinery cannot be appropriate judges of the relative excellences of pictures.

In conclusion, I may express the hope that your efforts to obtain the alteration in the classification will be successful; and that while photographic apparatus is reduced to its proper rank as a subsection of philosophical instruments, photographic pictures will be raised to the position which they have acquired by the recent progress in the art, by being put in the group of Fine Arts, which is the only place under which they can be consistently classified.—Your obedient servant,

Lyon Playfair.

To the Secretary of the Photographic Society of London.

The following letter has been addressed to the Society's Secretary, Dr. Diamond, to the Secretaries of the various photographic societies requesting an expression of opinion on this important question.

King's College, London, W.C., June 11, 1861.

Sir,—I am directed by the Council of the Photographic Society of London to invite the attention of the body of which you are the representative, to that portion of the Regulations of the Commissioners for the International Exhibition of 1862 which relates to the photographic art.

In the programme published by the Commissioners, Photographic Apparatus and Photography are classed in Section 2, among machines and mechanical processes, instead of in Section 4, in which are placed Sculpture, Painting, Engraving, and all those occupations to which the title of "Fine Arts" is usually applied.

The Council have been requested by the Commissioners to name from among their body a Committee, whose office it will be to take care that the interests of Photography and of its cultivators shall be properly represented in the Exhibition of 1862.

The Council, however, deemed it to be their first duty, before naming any Committee, to point out to the Commissioners the improper classification of the art, and to request that it should be removed from the class of machines and mechanical processes, to that portion among the Fine Arts to which it has so just a claim.

Enclosed for your perusal is the letter of the President of the Society to the Commissioners, and subsequent correspondence.

The final reply of the Commissioners appears to the Council to be so unsatisfactory as to compel the consideration, not only of the question of the appointment or non-appointment of a Committee, but also whether it will not be their duty to recommend those Members of the Society who look upon their art as more than a mechanical process to abstain altogether from exhibiting any of their works.

Before adopting so grave a resolution, they desire to have the advice of the Society of which you are the representative. They have placed the correspondence before the Councils of the French, Belgian, and other continental Photographic Societies, and requested their opinion upon the course which, in the interests of the art, ought under these circumstances to be pursued.

It is their wish that any resolution which they may lay before the Commissioners in their final reply, shall be the result of the united and deliberate opinion of the whole body of photographers, both in England and abroad.

Requesting you to lay this letter before your Society, and of favouring me with a reply at your *earliest* convenience.—I am, sir, your obedient servant, Hugh W. Diamond, M.D.,
Secretary to the Photographic Society of London.

The articles exhibited will, under the present arrangement, be divided into the following Classes:—

Section I.

Class 1. Mining, Quarrying, Metallurgy, and Mineral Products.
,, 2. Chemical Substances and Products, and Pharmaceutical Processes.
,, 3. Substances used for Food, including Wines.
,, 4. Animal and Vegetable Substances used in manufactures.

Section II.

Class 5. Railway Plant, including Locomotive Engines and Carriages.
,, 6. Carriages not connected with Rail or Tram Roads.
,, 7. Manufacturing Machines and Tools.
,, 8. Machinery in general.
,, 9. Agricultural and Horticultural Machines and Implements.
,, 10. Civil Engineering, Architectural and Building Contrivances.
,, 11. Military Engineering, Armour and Accoutrements, Ordnance and Small Arms.
,, 12. Naval Architecture, Ships' Tackle.
,, 13. Philosophical Instruments, and Processes depending upon their use.
,, 14. Photographic Apparatus and Photography.
,, 15. Horological Instruments.
,, 16. Musical Instruments.
,, 17. Surgical Instruments and Appliances.

Section III.

Class 18. Cotton.
,, 19. Flax and Hemp.
,, 20. Silk and Velvet.
,, 21. Woollen and Worsted, including Mixed Fabrics generally.
,, 22. Carpets.
,, 23. Woven, Spun, Felted, and Laid Fabrics, when shown as specimens of Printing or Dyeing.
Class 24. Tapestry, Lace, and Embroidery.
,, 25. Skins, Fur, Feathers, and Hair.
,, 26. Leather, including Saddlery and Harness.
,, 27. Articles of Clothing.
,, 28. Paper, Stationery, Printing, and Book-binding.
,, 29. Educational Works and Appliances.
,, 30. Furniture and Upholstery, including Paper-hangings and Papier-mâché.
,, 31. Iron and General Hardware.
,, 32. Steel and Cutlery.
,, 33. Works in Precious Metals, and their imitations, and Jewellery.
,, 34. Glass.
,, 35. Pottery.
,, 36. Manufactures not included in previous Classes.

Section IV.—Modern Fine Arts.

(*See Decisions* 111–123.)

Class 37. Architecture.
,, 38. Paintings in Oil and Water Colours, and Drawings.
,, 39. Sculpture, Models, Die-Sinking, and Intaglios.
,, 40. Etchings and Engravings.

Proceedings of Societies.

London Photographic Society.*

We resume the report of the meeting of this society, held at King's College on the 4th inst., Joseph Durham, Esq., in the chair.

Before proceeding to the electric light experiments we may refer to the specimens submitted to the attention of the society. Regarding the specimens spoken of by Mr. Shadbolt, it is unnecessary to say much beyond mentioning the fact that they were unquestionably the very worst on which to try a lens defining accurately on a mathematical plane, and a very crucial test for a lens possessing what is termed depth of focus; one being a view in a cemetery in which the lens was focussed sharply on a tombstone at no great distance; the inscription on this was very perfect definition, whilst all the tombstones from a few feet behind it were out of focus. The other picture was an architectural subject, but the focus was upon the corner of a building, so that its two receding sides rapidly ran out of focus. Mr. Bedford's pictures, with the same lens, were prints 11 in. by 9 in. of Ely Cathedral; one interior and one outside view, and were fine specimens of Mr. Bedford's skilful manipulation and judicious management. The focus of the lens was $12\frac{2}{3}$ inches, intended for pictures $8\frac{1}{2}$ in. by $6\frac{1}{2}$; the full aperture giving the interior in five minutes with a bad yellow light, is, we believe, $\frac{9}{10}$ in. In stating that the pictures were 11 in. by 9 in., it must not be understood that there was perfect definition over that space: the lens is intended simply for a whole plate, and does its work well over that amount of surface, giving satisfactory pictorial definition; beyond that space there was, of course, a gradual loss of definition and illumination. The well-known characteristics of the orthoscopic lens were sensibly apparent beyond the space the lens was intended to cover, and the marginal lines were curved outwards; this was, however, by Mr. Bedford's skilful management, reduced to a minimum over the more important parts of the picture. The work was, doubtless, excellent, both of the optician and the photographer; the marginal faults to which we have referred being inherent in that form of the lens, and not due to any imperfection in its manufacture. We have said more than we should have done on an apparently trivial subject, because we believe much misunderstanding and angry correspondence had arisen in connection with it.

In the course of the evening Mr. Sutton showed the first panoramic lens and camera made by Mr. Ross, together with the first negative taken with it. Various essential improvements had been effected upon those he had had made before, and he had every reason to believe most satisfactory results would be obtained. The negative was taken, we understand, on a tannin dry plate, and was exposed a minute-and-a-half. The definition and detail appeared very perfect. The view was taken from the roof of the laboratory at King's College, and included about an angle of 95°.

* Resumed from our last.

Mr. HEATH having read his paper descriptive of Professor Way's electric light (see p. 279), proceeded to show the difference in actinic character between the light thus obtained by means of the stream of mercury and that given by the carbon points in a Duboseq's lamp, which had been lent by Professor Farraday for the purpose, testing both by direct printing, and the mercury light by means of developed prints as we explained last week. The cost per hour, he understood, of charging the batteries, was about two shillings; and as a large number of printing frames might be hung round one lamp, the cost of printing need not be very heavy.

Mr. HUGHES having made his enlarging experiments,

Mr. MALONE referred to the former experiments of himself and others with the electric light. Interesting as the subject doubtless was, he did not think the experiments they had seen were sufficiently conclusive. He should have preferred to print a negative he had brought with him, which was the same as that he had before tried with the Duboscq lamp, and all the conditions regarding which he had noted carefully for comparison. The paper ought also to have been hung nearer to the light in both cases. He was not at all sure to what extent the glass shade over the mercury light acted as a reflector and gave it an advantage. These and other circumstances prevented the experiments from being of that comparative nature which was desirable, and, in his opinion, placed the carbon lamp at a disadvantage. He would therefore ask members to suspend their judgment. Regarding the question of cost it appeared that the estimate he had before given as an approximation, was not very different to that now arrived at. He had stated that the cost of charging the batteries was about ten shillings, and as they lasted four or five hours the result was the same as now stated, notwithstanding that at that time Mr. Heath endeavoured to throw cold water upon the idea as expensive and impracticable. These figures were not at all conclusive or reliable; the truth was, no one knew exactly the cost without more experiments, and more careful calculation than had yet been made. Having the utmost familiarity with the subject, and every facility, he was engaged at the present time on some more conclusive calculations to determine the cost. He was not at all sure that the mercury lamp would prove the best, and in comparing it with a Duboscq lamp, they should bear in mind that there was now an improved form of lamp with the carbon points, that of M. Serrin. The mercury might also prove dangerous to health. He knew one gentleman who having been experimenting with the Way lamp, suffered in health next day from its effects.*

Mr. HEATH was not there to recommend that lamp to photographers as best for their purpose, but rather as the exponent of its characteristics, as he knew something of it and its inventor. In his statements regarding its superior actinic character, he had simply quoted Dr. Gladstone, but he thought there could be no doubt of that fact. Regarding the trial referred to, the lamp was quite at Mr. Malone's service for the purpose when the proceedings were concluded. As to the glass over the mercury light acting as a reflector, he thought it unquestionably acted much more certainly in absorbing and dispersing light.

Mr. MALONE thought there would be both reflection and refraction. In any case the experiments were not comparable. He felt it his duty to make these remarks, otherwise he might be charged with having by his silence endorsed the conclusions put forth.

Mr. HEATH thought Mr. Malone need be under no apprehension about his silence in that room being misappreciated or misconstrued. Regarding the comparative nature of the experiments, they were not intended as comparative. The idea had just occurred to him that day, to ask Professor Faraday to lend the Duboscq lamp to give additional interest to the experiments. It had just been named to him in regard to this lamp, which had only recently returned from Paris, that M. Duboscq had admitted that there was no comparison between the amount of actinism in this lamp and his own, as illustrated by their respective spectra.

Mr. MALONE was glad to hear it. Did he refer to the length of the actinic part of the spectrum, or to intensity and rapidity of action?

We understood the answer to be that intensity was meant.

Mr. MALONE remarked, that it might be interesting to state that nothing gave a better actinic light for a short time than the burning of phosphorous in a jar of oxygen.

Mr. HIGHLY remarked that Mr. Serrin's lamp was no improvement on Duboscq's as regarded quality of light; the only difference was in a mechanical arrangement to keep up continuity, which in Duboscq's required to be done by an assistant.

Mr. HUGHES called attention to the solar camera, and explained how the excess of diffused light from various sources had prevented the experiments in enlarging, just attempted, not entirely satisfactory. The conditions also were so different in the use of solar light at an infinite distance and a source of light close to the instrument, that to succeed in enlarging by artificial light would require all the appliances being re-arranged to suit the conditions. The importance of facilities for rendering them independent of solar light for enlarging purposes could not be overrated in a climate like ours, where the meteorological conditions were so variable and uncertain. He regretted that time and opportunity had been wanting to secure the conditions of success that evening with the solar camera, as he felt convinced that this instrument had not received that attention its importance demanded; he did not believe that for the production of life-size portraits there were any other appliances in existence that could compare with it, and he spoke advisedly in saying so.

Mr. SHADBOLT had long waited for this opportunity, and now could not allow it to pass without publicly protesting that with such an instrument it was impossible to produce a sharp image from any negative. The condensing lens was non-achromatic, and a blurred image must result from its use. It was moreover placed in the worst possible position to produce good results. It should be—

Mr. HUGHES explained that at that moment it had just been placed there without intention, and was not in the position used for working.

Mr. SHADBOLT thought it was placed as when in use. However, the focus of the condenser, instead of being on the front lens, as recommended, ought to be on a point somewhere between the front and back lens of the copying combination. The subject was too long for discussion then, but he threw down the glove, and hoped Mr. Sutton would take it up.

Mr. SUTTON simply denied the accuracy of every one of Mr. Shadbolt's statements. He had given the subject much study, and knew of what he spoke. The condenser need not be achromatic; and its focus was in the right place. In short, without attempting to go into the subject at that hour of the night, he would content himself by saying he denied every statement Mr. Shadbolt had made. He was wrong altogether in the whole question.

After a few further remarks the proceedings terminated.

NEWCASTLE PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on Friday evening, the 7th instant, in the Tower, New Bridge Street, Mr. G. C. WARREN, one of the vice-presidents in the chair.

After the preliminary proceedings

The CHAIRMAN called attention to a circular received by the Secretary from the Manchester Society, and concluded by expressing a hope that not a few of the members would contribute. He then pointed to the several specimen prints from the negatives obtained by the photogen, as exhibited at the last meeting of the Society, and referred to the remarks made by the editors of the photographic journals, to whom prints had been sent, all of whom coincided with the opinion expressed by the Experimental Committee.

Mr. LAWS read his paper on "Transparencies." (See p. 280.)

After an animated discussion, Mr. WARREN gave a short description of the various methods of intensifying negatives, and a model mode of transferring the negative film from glass to paper and other substances.

A discussion ensued.

Several members at a recent meeting having complained of the collodion film splitting from the glass whilst the negative is being dried, Mr. Warren suggested to the meeting a plan he had successfully adopted in such cases. Should the film have the least tendency to split he immediately flooded the plate with alcohol, this driving the water out of the film permitting the varnish to be poured on; the plate being in a moist state, the varnish occasionally dries dead, but this is of no consequence. By this means he had saved many negatives that

* We may remark that the gentleman referred to was Mr. Bedford, who felt unwell the day after his printing experiments with one of these lamps. It is but fair to add, however, that Mr Bedford explained to us that the lamp was confessedly an imperfect one, and out of order, the escape of mercurial vapour being an accident rather than a necessity of the apparatus.—ED.

otherwise, owing to the bad quality of the collodion, would have been entirely destroyed.

After the usual votes of thanks the meeting adjourned till the first Friday in July, when it is proposed to take into consideratien the propriety of adjourning the meetings during the summer months as is usual with other societies.

Mr. North has promised to read a paper at the next meeting on "The Construction of Glass Houses with especial reference to the Arrangement of Light."

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 11*th June*, 1861.

The continual suggestions of new formulæ, new methods, and new processes, implies a certain amount of imperfection in the best, even, of those at present adopted. It is not improbable that this chronic dissatisfaction will lead to a complete revolution in our material and *modus operandi*. Why collodion should be so capricious as it shows itself to be in so many operator's hands I cannot divine. Seeing that many photographers, not remarkable for any superiority in genius, plod on year after year in the same routine, without varying or abating one jot of the zeal or success. Failure and dissatisfaction I suspect, proceeds, in very many cases, from over-refinement; from expecting too much, nay everything, from the collodion, or the nitrate bath, or the toning, when, after all, the secret of success lies in none of these exclusively, but in tact and judgment in the right employment of them. I am led to these remarks by the contemplation of a marvellous specimen of photographic portraiture, a portrait of Lord Brougham, by Mr. Mayall, which is the admiration of our connoiseurs, and would seem to realize all that can be expected of the photographic art, and at once silence all the discontent and dissatisfaction expressed at the imperfection of the means. With such a result before us as this picture presents, complaints against collodion, &c., would indeed seem idle; for it is difficult to conceive how any finer result can be arrived at, whatever may be the future improvement in material or appliances.

Both M. Van Monckhoven and the Abbé Desprats, to whom we already owe so much, have returned to the much-vexed questions of collodion and developing agents, with what results the sequel will show. From an intimation, however, recently set forth in your journal, it would seem likely that collodion will be superceded, and with it the vexed nitrate bath—let us hope the news is not too good to be true.

Messrs. Recolz and Fontenay have produced a new alloy which is applicable to the production of coins as well as to many important industrial purposes. It consists of one-third silver united with 25 to 30 per cent. of nickel, and from 37 to 42 of copper. Its preparation is a true chemical *tour de force*, for the elements of which it is composed, if merely melted together, yield a product void of homogeneity—an imperfect mixture, rather than a combination. To make it combine intimately, Messrs. Recolz and Fontenay have recourse to certain fluxes, which they do not specify, and also to phosphorus. The alloy thus obtained is at first very brittle; it cannot be fashioned under the hammer, nor drawn into wire, and is altogether deficient in those properties most required in working metals. But it is sufficient to remove the phosphorus if the compound be re-heated, after which the alloy perfectly resembles a simple metal, and presents in a very high degree the qualities to which the precious metals owe their superiority. It resembles platinum and silver of $\frac{800}{1000}$ in colour: it takes a very brilliant polish. Its tenacity and hardness are extreme. It is ductile, malleable, and very difficult of fusion; very sonorous, unalterable in the air, and attacked only by the most energetic reagents. It has no odour, and its specific gravity is but little inferior to that of silver. It is easy to estimate the important part such an alloy is calculated to play in the industrial arts, and especially in the silversmith's art—in, to a great extent, replacing silver, of which its price is 40 per cent. less, and as its hardness gives it a marked superiority. Again, articles which are merely silvered or gilt have, it is true, a great advantage in their low price; but they quickly deteriorate, and can be re-silvered or regilt only a very few times, after which they must be replaced by new ones, and, in the long run, entail such an outlay as to confirm the old adage, that "the cheapest is the dearest in the end." Moreover, Messrs. Recolz and Fontenay propose to substitute their new silver alloy in coining pieces of money of less value than five francs. Under this point of view, they say, the alloy presents the following advantages:—"Its preparation and application require a plant and special precautions which render counterfeiting extremely difficult. The nature of its constituent elements is such that the cost of the necessary refinings to bring it to a high standard deprives it of any advantage in exportation. Its hardness, much greater than that of silver, which reduces the necessity now experienced for recoinage, as the coins would be very slow to wear away.

A Parisian architect has made a very ingenious suggestion for the cure of many of the evils inflicted upon citizens by the present mode of arranging chimneys, and more especially to remove the present architectural eye-sores caused by uncouth and hideous chimney-pots. He proposes to construct at the roof of an edifice a smoke chamber furnished with a central orifice, to which any desired architectural form may be given. Into this chamber all the chimneys of the building are to be conducted, and there discharge their smoke, putting an end at once to the nuisance of bad draughts, smoky chimneys, &c.

The heat of the smoke-chamber may be economised.

The approaching hot season renders any suggestion for the cure of hydrophobia interesting. Dr. Rodet, of Lyons, who has for a long time devoted his time to researches for an antidote to various animal poisons, as in farcy, glanders, syphilitic virus, &c., employs topically, a liquid containing perchloride of iron as a basis, which he has found very efficacious, as it destroys the virus even if applied two hours after the bite of the rabid animal, and it seems not improbable that its action would be effectual even if applied four or six hours after the wound is inflicted.

M. Th. du Moncel has made some interesting researches on the transmission of electricity through the earth. He states that upon connecting, by means of an isolated wire, two iron plates buried in soils differing in constitution, either with respect to humidity, or in physical or chemical condition, a telluric current results, which is much more energetic when the difference of humidity in the soil surrounding the electro-positive plate is greatest. This shows that the intervening current in electric transmissions through the telegraphic circuits, materially alters the conditions of resistance of these circuits, and also the conditions of constancy in the currents transmitted, according to the manner in which the pile is placed in relation with the buried plates. When the telluric current travels in the same direction as the current of the pile, the current of polarization due to the polarization of the buried plates is destroyed, and consequently the resistance of the circuit is found to be diminished at the same time that the intensity of the current acquires most constancy. In the opposite case, the telluric current is added to the current of polarization, and the injurious effects due to this latter current are found to be augmented. The result, therefore, is, an augmentation in the resistance of the circuit which continues augmenting with the duration of the closing of the current, and which is much greater relatively as the length of the circuit is more considerable. As a practical conclusion of these effects, M. du Moncel concludes that the choice of the pole of the pile of the line which must be put in connection with the earth at the station of departure in telegraphy, is not a matter of indifference, and must be determined by the direction of the telluric current which pervades the line. If this current proceeds from the station of departure to the corresponding station, the negative pole of the pile must be connected with the earth, in the opposite case, it must be the positive pole.

PROFESSIONAL PHOTOGRAPHY IN THE MAURITIUS.

"Photographers of England,
Who live at home at ease,
How little do you guess the bores
We have across the seas."

MR. EDITOR,—I recollect reading some time since in your journal a description of a scene in a photographer's studio at home, I think your readers may possibly be amused with a colonial one. In England the photographer well established knows little of the difficulties of the "delightful art" as carried on here with even pecuniary success, and the shifts one is compelled to resort to.

The ship has not arrived with your last order, or having arrived, you find your chemicals decomposed by the heat of the hold, your ether evaporated, your acids (having been carried on deck at your risk as per bill of lading) thrown overboard on the passage. You go to a chemist, who in consideration of ten dollars (£2) per lb. *obliges* you with a small quantity of ether. You try it and find it sp. gr. ·870 and have to set to work to wash and rectify it. The same with your alcohol. Your nitrate of silver is all done, and none to be bought; you procure nitric acid at five shillings a pound, and with sterling silver make it in a pipkin. Although a cotton growing country, you can get no cotton wool, sulphuric acid is five shillings a pound, and you are at a standstill for pyroxyline. At length you make your gun cotton with darning cotton (and a good shift too) and you are finally *en train*. Having secured an *atelier* at £12 per month: and as you fancy yourself a sufficiently good linguist to meet conversational business exigencies, there are no further difficulties, and you go a-head.

SCENE 1st.—Photographers Studio at Mauritius, Thermometer 96°.—Enter two young ladies (brown) in white dresses.

"Bon jour, Monsieur, moi besoin vous tirer mon portrait." (Good morning sir. I want you to take my portrait).

"Certainly, but I am sorry to say I shall not be able in white dresses to give you satisfaction; if you will come in dark or coloured dresses I shall have much pleasure."

"How much must I pay for that size?"*

"Five dollars."

"Oh! that's very dear; I am not able to pay so much as that. I will give you twenty-five francs" (10s.).

"Sorry to say I cannot," &c. &c.

"Well, I will give your price if you will put it into a pretty box the same as that."

Agreed, the ladies return in dark dresses, the portraits are taken and shown.

"Oh! I am not so ugly as that. Look how large the mouth is, and the face quite black, and little specks in my eyes. Mon Dieu! look at the hair, its all white," (she has not spared the cocoa-nut oil to make her wool lie smooth, and of course the light is thrown off in a patch on the front of the head). Finally, by means of the pencil I make the picture no longer a photograph, they retire satisfied.

Next we have a group of young gentlemen from the garrison, who at once monopolise the *salon*.

"Let me—ah!—see your pictures—ah;—What's the pwice of this—ah!"

"Ten shillings."

"Monstwos—whoy, befaw we left; Jenkins of ours had himself taken at some fellahs in Wegent Street for a shilling, spwendid picture, in full uniform, couwdn't think of giving such absurd pwices as yours. Come Bob, lets go and get some bittah beah.

Exeunt having made an impression on those waiting, and causing them to think you were imposing on them.

Then a lady with a child.

"I wish you to take my little boy, I have promised to send his picture home to his grandmamma; I should like you to take him standing to show how tall he is, and, that the picture may look natural, playing with his dog, and his ayah (nurse) standing behind him.

Here is a complication of impossibilities, and yet you are expected to make a good picture; the child is fifteen months old, can just stand, is very fair with light eyes, and has a light blue dress on. The dog is a white poodle, and the nurse is a black Indian woman, with a white muslin wrapper thrown round her, and over her head, and looking as if she fancied you were going to shoot her from the mouth of the camera; the mother and two or three friends insisting on looking on, because (they say) the child will not be quiet unless they are there; however, by good luck, patience, and perseverance, you get a picture. Such are a few of the scenes taking place every day, not at all exaggerated.

The coloured population you cannot please unless you make them fifty per cent lighter than they really are; the English, who have friends in England, have pictures sent them which there cost a few shillings; and, forgetting the difficulties you labour under, and the comparatively few sitters you have, they imagine your prices exorbitant. "Why we have only to sit a few seconds, and you can earn so much." Another will come in and want views of the country: your negatives have to be taken under great disadvantages, in a country I admit abounding in most romantic scenery, but without any accommodation, and to move about much is ruin both to your pocket and your temper; besides, every person has his or her particularly beautiful view that you must take to make the series complete. I would advise any person contemplating going abroad to think twice 'ere they do it—for my own part, were I not fixed, and could get out of it, I would prefer being a bricklayer's labourer to

A CREOLE PHOTOGRAPHER.

Mauritius, August, 1860.

* It is not necessary to give the French patois of our correspondent's fair (?) interlocutors.

Photographic Notes and Queries.

STAINS AND STREAKS.

SIR,—A long paper has been read to prove that stray light in the dark room is the cause of streaks on the sensitized plate. A long discussion followed doubting the fact; and a leader winds up by denying the assumption. Allow me to put in a streak of advice. Let a ray of light into your dark room, or if you like, leave the door ajar, and notice the effect. Five minutes devoted to this experiment would settle the point to the satisfaction of all. MUS.

Mous, June 1st.

[It is not doubted that diffused light in the dark room may, under certain conditions, be a cause of streaks: we know it to be so. It is only denied that it is the universal cause, or even a common one. Actinic light has no business in a dark room; but when present, streaks are not the most usual sign it gives of its presence.—ED.]

PHOTOGRAPHS ON IVORY.—We have recently had our attention called to some photographs on ivory by Mr. Perry, who, as will be seen from our advertisement columns, has just removed into Piccadilly. The process is a secret one known only to Mr. Perry, the inventor, who, however, expresses the fullest assurance of its permanence. They are coloured with much care, and have all the delicato and transparent effect which generally characterizes ivory miniatures. We have not seen any uncoloured copies, and cannot therefore speak of their photographic merits.

Talk in the Studio.

The Art Season is not, so far, at all favourable in its aspect as compared with last year's. The sales being generally few both at the sale-rooms and the exhibitions.

Leslie's Paintings.—The proposed exhibition of these works at the house of the Society of Arts has been abandoned, so many of their proprietors appearing reluctant to contribute to the collection.

The Society of Arts Conversazione.—Some fine transparent enlarged photographs, by the oxyhydrogen light, were exhibited on this occasion. A still more interesting meeting took place at South Kensington on the 1st of June.

Photographic Cherubs.—We were much amused by a photograph recently executed by Mr. A. H. Wall, of Old Bond Street, in which a number of heads, borne, cherub-like, on wings, were grouped against a back-ground of sky and cloud. The familiar features of Paul Bedford, with his hat cocked rakishly aside, seemed peculiarly ludicrous when associated with his angelic appendages; and Toole, the ever-funny yet never unnatural Toole, seemed soaring away as if legs were things undreamt-of in his philosophy. Rosina Wright, *without her legs*, was hard to be conceived, and we could not regard her wings as compensation for a loss which would be quite a national calamity. Pretty Kate Carson as an angel was not half so charming as she is in all the charms of womanhood; and sprightly little Marie Wilton seemed to think her position one demanding very solemn thought. A dozen of our popular actors and actresses, in short, are thus grouped; and the effect is certainly provocative of laughter. Of course, the method adopted is similar to that by which the large-headed, small-bodied, portraits now in the shop windows are produced, viz., printing the heads without the bodies, and painting in the wings with Indian ink.

Stereographs of Dutch Scenery.—We have received from a correspondent at Amsterdam a parcel of very interesting stereographs, consisting chiefly of scenes in and about Amsterdam and Haarlem. They are the first Dutch photographs which we remember to have seen, and are full of interest; the quaint style of the buildings, so like those still remaining of the time of Queen Anne in this country, and the prevalence of the universal canal, add much to the value of the pictures. For the most part the photography is very good; vigorous, yet full of detail. A few are by the collodio-albumen process, as given by Mr. Sidebotham in our pages some time ago; but the majority are by the hot water process as suggested by Dr. Ryley, and subsequently by Mr. Parry, and are sufficient to vouch highly for the valuable results obtainable by that process.

To Correspondents.

Sol.—We are glad that our suggestion has enabled you to apply a remedy; we felt convinced that the vulcanized india-rubber was the cause of the annoyance.

Exeter.—The size and shape of the mirror of the solar camera are, we suppose, those conceived to be by the inventor the most convenient: it is quite possible that an improvement might be effected. The focus of the condenser is recommended by the inventor to be kept upon the front lens; but, as we have before said, we should conceive that it ought to be on the same point as a central stop between the lenses. Of course the movement of the copying lens by means of the rack and pinion will alter its relation to the focus of the condenser, but there is an arrangement for regulating that, which, we presume, should be done the last thing.

Mr. Polman, of the Hague, has been recommended the use of some apparatus to prevent photographers breathing the fumes of ether and other deleterious chemicals whilst operating. We have not heard of such apparatus. We shall be glad if any of our correspondents can give information on the subject. We do not know of any method of obtaining Rouch's collodion in Holland, except by sending for it to this country direct. We are glad to hear of your successful practice of Bartholomew's, or Hannaford's modification of the Fothergill process, and of the aid you derive from the News.

X. Y.—Do not tone so deeply, a little warmer tone will be much more pleasing.

M. J.—We prefer cyanide for fixing positives, and hyposulphite of soda for fixing negatives. The surface of the image is generally a little browner when fixed with the latter, and this is as much an advantage for a negative as it is a disadvantage for a positive.

L.—You can measure the height of distant objects by the aid of photography approximately, if you know the distance you are from the object, and it be on tolerably level ground. It is a simple rule of proportion. Measure the height of the image produced, and then calculate, as the length of focus of the lens is to the image produced, so will be the distance from the camera to the height of the object required. Thus if with your lens of 4½ inches focus, you get an image of a building 2¼ inches high, at a distance of a hundred yards; the height of the building would be fifty yards, fifty bearing the same relation to a hundred which 2¼ does to 4½. Bear in mind this will be only a tolerably near approximation, unless the ground be quite level, and you calculate the exact focus of the lens for the distance.

Philip.—Transparencies on glass generally exhibit much greater delicacy and detail, than proofs from the same negatives on paper.

Amsterdam.—We are much gratified by your letter, and the stereographs. Independent of the merit of many of the pictures, the subjects are full of interest, and are to us entirely new. There are two or three suggestions we may make, which will make your work still better. Although you have largely avoided the faults common to dry processes, yet a little more exposure would still be beneficial in many instances. But the chief point to which we would call your attention is the fact that whilst many of the slides have more of one side of the picture in one half, and more of the other side on the other half, it is generally in the wrong directon. Thus if the amount of subject be not exactly the same in each half, the variation should be that the right picture should give a little more on the right side, and the left picture a little more on the left half, just as would really be seen by each eye separately. In yours unfortunately the converse is true; you have a little more of the left side of the subject which would be seen by the left eye mounted on that end of the slide which is seen by the right eye, and *vice versâ*. Read Mr. Shadbolt's remarks on the subject at a recent North London meeting. The stereoscopic effect of your pictures will be materially enhanced by attention to this matter. Your pictures being sent as a present rather than for criticism, we have felt some hesitation in referring to any points in which they might be improved; but we feel assured that you would rather be informed of a point whereby you may materially improve them than not. We thank you for the kind letter and present of so many interesting slides.

Seaside.—The patent starch, in powder, and colourless, that is without the addition of blue, is the substance we have found best as a paste for mounting photographs. To make the paste, take a teaspoonful of the starch powder and moisten with the smallest possible quantity of water, about a teaspoonful, then pour on boiling water, stirring rapidly, until the paste is of the consistency of a jelly. We have made it in a marmalade jar, and a tea spoonful of starch will make a jarful of paste. Its keeping properties much depend on temperature. In warm weather not more than two or three days. It is best used fresh.

Photo.—Use a good bromo-iodized collodion; develop with iron and work in a good light for instantaneous effects. The best lenses you can get, and the largest stop with which you can get definition, are suitable for the purpose. The lenses of various good makers will answer; we have more than once mentioned those we use ourselves and find very rapid.

E. A.—We cannot undertake to say which is the best dark tent, inasmuch as we have not tried all. We recently described Smart's, which appears very good indeed. We have before described Leake's, which is cheap and useful for small work such as stereo pictures, and we have known 10 by 8 pictures worked in them. We shall shortly describe a very excellent one just making by Mr. Rouch, and also some others. By all means tone and fix separately, using the alkaline gold toning process.

M. B. Joye.—We will insert your letter next week, as interesting to those concerned. See article on the use of gallic acid in connection with Fothergill plates. We do not see that you will gain anything by changing your collodion. We do not recognize the spots you speak of, nor can we without seeing suggest cause or remedy.

N.—There is no doubt that the liquefaction is spontaneous. In fact such a result could scarcely fail to occur at some time, as it is only in virtue of its deliquescent character that chloride of calcium keeps paper dry by absorbing its moisture. Super-saturation, must necessarily only be a question of time. It may be desirable, as you suggest, that the matter should be better known. Will you write a statement of the case, or shall we make an abstract of your letters?

F. E. G.—We have been much engaged, and also from home. We will send in a few days.

Despair.—We see no reason whatever, why you should despair. Each one of the numerous specimens sent, possess some good points, and if we are not mistaken we have seen some better prints from some of the same negatives, in a specimen case. We have not time or space to enter into minute criticism this week; but may do so another time. The chief fault is too much light right in front of your sitter, which flattens prominent features; a little under-exposure seems to prevail also. Observe carefully the best works of the best artists, and see in what they differ from your own. We think you will have ability enough to improve considerably still.

G. Smith.—You mistake the meaning of the term; there are no signs of solarization about your picture. Solarization is always most manifest in the parts of a picture which are most illuminated, such as the sky; and results in thinness of image. Your sky appears very dense. The foliage exhibits signs of having moved very much; but if, as you state, there was no wind, it is the result of very imperfect focus. There is no part sharp, and if it be not the result of very imperfect focussing, it is a very bad lens. The negative is also under-exposed.

William Dodgson.—We are obliged by your communication, which shall receive our attention.

J. A. Hurd.—You are in error in your estimate of the relation of specific gravity in alcohol and what is termed "proof." Proof spirit has a sp. gr. of ·920, or a fraction less, but you cannot arrive at the sp. gr. of spirit a given strength over proof, say 60, by deducting that from 920, because the figures refer to two distinct things. Spirit 60 over-proof has a sp. gr. of nearly 830; spirit of 63 over-proof has a sp. gr. of nearly 825; and that 65 over-proof a sp. gr. of about ·820. We are not now speaking by the card, as to fractions, but you will get the figures from Syke's hydrometer tables. The strengths we have named are easily obtained, and are near enough for practical purposes. 2. We have never tried the spirit you name; but it is quite possible that it would answer the purpose perfectly. By redistillation over quick lime you can obtain a sp. gr. of ·805 from spirit 60 over-proof. We believe Mr. Hardwich recommends redistillation from sulphuric acid. 3. We shall describe the contrivance you name, shortly. 4. The darkness in the hands and features to which you refer, may proceed from various causes, such as bad lighting, under-exposure, or a collodion wanting in intensity. We presume, from your remarks, you are speaking of positives on glass. If you are, the formula given is altogether an error. You may use the collodion named without any dilution with alcohol and ether. It is a common error with persons who have not worked the positive process to recommend a thin collodion.

An article on "Depth of Focus," and letters on the same subject, together with several other articles and letters are in type, but stand over for want of space.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 146.—*June* 21, 1861.

DEPTH OF FOCUS: WHAT IS IT?

It is a trite saying, that almost all controversies arise out of the erroneous use, or misconception, of terms. An incidental discussion, which arose at the Photographic Society the other evening, on the subject of what is termed "depth of focus," and which was but the fresh "cropping out" of an old dispute, certainly seems to come under that class of controversies.

Mr. Shadbolt declares the phrase an absurdity, and the thing an impossibility; and

> "What 's impossible cannot be,
> And never, never comes to pass."

Mr. Sutton affirms that the thing does exist, and that without it we could have no presentable picture. He not only affirms that the thing exists, but that there are two distinct forms of it, one of which is legitimate and desirable, and the other the result of imperfection and error in the manufacture of lenses; that a bad lens might give depth of focus with full aperture, but that a good one would give depth of focus by using a sufficiently small aperture.

Now when Mr. Shadbolt exclaims that it is utterly impossible to get two objects in different planes in perfect focus at the same time, he simply states what no one, using the word focus in the same absolute sense in which he uses it, can for a moment deny; but tying the word down to a use a little more absolute, we may further affirm that it is impossible to obtain a perfect focus at all. It is clear, then, that we must use the word relatively. Absolute focus being impossible, the question resolves itself into one of sufficient definition. That a lens the most scientifically perfect, giving microscopic definition to objects on a mathematical plane, will give all other objects more or less out of focus, and that in a most unmistakable manner, there can be no doubt; but whether such a lens is, after all, the best for the purpose of a photographer, is open to considerable question.

The word focus having an absolute sense as referring to the circle of least confusion, or the point at which the rays cross, exception may possibly be taken to the term "depth of focus" as it may be said to be referring to the depth of that which, strictly speaking, cannot have depth. It is possible that the word "definition," as having a more relative meaning might, with advantage, be substituted for the word "focus," and the phrase "depth of definition" be used to describe the quality in discussion. The phrase would imply not depth of perfect focus, since that cannot exist, but such amount of definition through a given space as shall be necessary to meet the exigencies of pictorial art.

Mr. Malone rightly remarks, that we must look at the question practically, and in relation to the necessities of photography, and these necessities are, nine times out of ten, pictorial effect. Mr. Shadbolt thinks he is true to art as well as science when he states that he requires a lens to approximate to the human eye, which can only have objects in one plane in focus at the same time. But the human eye will, in the fraction of a minute, adjust itself to every plane of view before it, and produce on the mind the effect of perceiving the whole at once. The painter who sits down to paint a landscape, would never dream of fixing his eye in one focus and never altering it during the progress of his picture. His object is to get such a picture as the eye sees, as it constantly adjusts itself over the landscape before it. It is true he does not attempt to paint every object with equal perfectness of definition; he does not see every object so, however he may vary the focus of his eye. There is an increasing veil of atmosphere between him and objects at each gradation of distance, which, whilst it does not alter or even blur forms, prevents them from being "made out" with the minuteness of foreground objects. All the objects he can define perfectly with the eye, he does not necessarily define as perfectly in his picture, because some require to be subordinated. All foreground objects, and especially those intended to concentrate the interest, will be more crisply defined, more vivid in contrast of light and shadow, and more brilliant in colour than the rest. Each receding plane of distance will be less sharply defined, less marked in contrast of chiaroscuro and colour, until, in the extreme distance, details and contrasts are almost entirely lost. But this absence of definition is nowhere of the blurred character which is presented by objects entirely out of focus, and is produced by a lens as perfectly corrected as possible, when used without a stop.

There can be no doubt that the exigencies of pictorial art demand the presence, to a certain extent, of this quality, which has been called "depth of focus." A portrait with the eyes sharp, and the nose, ears, and various locks of hair little more than indistinct blurs, is something very hideous; and yet we have seen this where a lens of short focus, defining very accurately objects on a mathematical plane and nothing more, has been used. A landscape with a few objects crisp and well defined, and the rest a mass of indistinctness in which neither form nor texture are indicated, is simply intolerable and worthless. Some depth of definition then is absolutely necessary to pictorial effect. A portrait lens must have sufficient depth to give, with judicious management, all parts of the body with something like satisfactory definition; all parts of the head should, at least, be fairly defined, so that when the focus is on the eyes, the nose and retiring locks of hair may not be perceptibly out. In a landscape much greater depth is necessary, and in view lenses always exists to a greater or less extent, and is also more readily obtainable by other means than in the case of portraiture.

There are several sources from whence this depth of definition may be obtained. It may sometimes be obtained from what is called a bad lens, that is, a lens imperfectly corrected for spherical and chromatic aberrations. If it be thus obtained it may, by rare accident, be in just the desirable ratio for artistic purposes; but it is more frequently at the entire expense of anything like defining power at all, and renders the lens comparatively worthless. In the ordinary view lens a certain amount of depth of definition necessarily does exist, from the simple fact that it is impossible to correct it entirely for spherical aberration, but the aim of the optician is always to correct it as perfectly as he can. Depth can also be obtained in the best corrected lenses as suggested by Mr. Sutton, by the use of small stops; by their use the rays of light are made, in crossing, to form a much more acute angle, so that definition over a greater depth of space is obtained. Depth of definition can always be obtained by retiring sufficiently far from the nearest object to be taken, so as to render the distance of all objects beyond, as nearly *nil* as possible, in relation to the length of focus of the lens.

As regards the last-mentioned method it is clearly out of the question to think of adopting it to any extent in portraiture, as it would involve the use in all cases of very long rooms, and of lenses of very long focus. And it is also frequently difficult, even in landscape work, to use it largely. The use of stops for the purpose is doubtless very legitimate, and often desirable. But even this has its limits, as the use of very small stops not only involves very considerable loss of light, but also materially diminishes the relief and boldness of the picture, giving it a flat and map-like effect; if, moreover, the aperture be reduced too much, we have not only these evils, but actually err on the other side, and obtain definition of nearly equal distinctness in foreground objects, and those perhaps miles away.

The use of bad lenses seems a thing unnecessary to discuss. No workman would willingly use a bad tool; and where this badness arises from incapacity or carelessness on the part of the maker, although it may now and then, just by accident, give a near approximation to desirable results, it cannot be relied on, and must be ignored as out of consideration. But there are good lenses which possess this defining power over a considerable depth, without losing in an appreciable degree the power of giving the best definition to objects more in focus. It is unnecessary to discuss, nor would it profit the majority of photographers to know, whether this quality is the result of over-correction for colour, or under-correction for spherical aberration, or both; or the result of a judicious antagonism of forces on the part of the skilful optician. But we think it important in the interest of those who, in practising photograpy, aim at producing pictures which shall possess definition over as great a depth as the artist would give it in his painting, to state that lenses with such defining powers exist. And that if the productions of those opticians who, in manufacturing their lenses, consider the work they are to perform, and who therefore give to a lens intended for such mechanical purposes as copying, a power to define as accurately as possible a mathematical plane and nothing more, but also give to lenses intended for the production of pictures having different planes of distance, sufficient depth of definition to do the work when judiciously managed, satisfactorily; if, we say, such lenses are to be stigmatized as bad, then we must confess our conviction that art-photographers will for many purposes decide to use such "bad" lenses: and, in the interests of art, we can but commend their decision. We may add our conviction, however, that the term "badness" is in such cases entirely a misnomer, and that such lenses can only be expected from the hands of the very best opticians.

INSTANTANEOUS PICTURES: STEREOGRAPHS BY MOONLIGHT, &c.

In our recent visit to the Birmingham exhibition we experienced that rare thing, a new sensation. Arrived at Aston Hall, accompanied by our good friend Mr. C. Jabez Hughes, we had, in obedience to the placarded invitation, "This way," traversed the "Arctic Regions in Winter," and the same scenes in their summer aspect, and having passed through the Stalactite caverns and some other unknown or unnoticed regions in our search for the photographic department, we found ourselves in a large hall in which, standing solitary and alone, were two handsome, circular stands of stereoscopes, exhibited, as we afterwards understood, by Mr. Breese of Birmingham.

We sauntered somewhat indifferently up to them, being in truth much more anxious to see a good display of solar camera pictures, which as yet we had looked in vain for. We had, however, scarcely fixed our eyes on the first stereoscope, when we were startled entirely out of our propriety by the exquisite picture before us. The scene we were familiar enough with, both in fact and in the stereoscope. It was a view of Fountain's Abbey; but instead of merely the picturesque old ruin, here we saw running water which really was water, bright, sparkling, transparent; we saw an exquisite sky with light delicate clouds, and the whole picture suffused with atmosphere in a degree we had never before seen in a photograph. Let us not be misunderstood: we are not disparaging the gems of Wilson and some others; but these were exquisitely printed transparencies from negatives equal to the best of Wilson's. When this fact is realized, our readers will understand something of the charm of the picture before us. "Come here," we quickly exclaimed to our companion, "here is something wonderfully beautiful!" "Nay, but come here," was the rejoinder, "nothing can surpass this!" Each picture we examined seemed but to awake new feelings of surprise, each being marked with some new feature of wonder or beauty.

A landscape view near Sydenham, with the Crystal Palace in the distance, was, perhaps, one of the most beautiful. Words fail us to describe the exquisite delicacy and ethereal charm of this picture. Those of our readers who remember Martin's picture of the Plains of Heaven, either in the original painting or the engraving, will recall the glorious white palace in the distance, so radiant with light that it seems to mingle with the effulgent atmosphere. Just such an effect is produced in the slide we refer to, the fairy-like structure so light and ariel, is yet so distinctly rendered against the still more distant and slightly-clouded sky. Stormy seas, under skies, with storm-driven clouds flying over them, most perfectly rendered, next met our attention. Setting suns, surrounded by clouds, the whole repeated by reflection in the water beneath, such as Wilson loves to depict. An instantaneous waterfall, in which the sparkling waters are crisp and clear as threads of silver; the "woolliness" which arises from moving water, where a prolonged exposure is necessary, being entirely absent. Scenes of still life, presenting the most delicate and exquisite gradations. A slide before us is a strikingly-beautiful subject of this kind: it consists of a simple but skilfully-arranged group of objects on a marble chimney-piece, in which there is but one colour, and that colour, to use a solecism, white; difference in surface or texture is almost the only source of variety. It consists of a parian statuette under a glass shade, a glass of water, a cut-glass bottle, and a cut-glass lustre, a chased silver flagon, and a pearl shell, arranged, as we have said on the white marble chimney-piece, and a looking glass for background. Here we have the white of parian, of cut glass, of water, of silver, of pearl, and of marble. A most unpromising photographic combination: but the result is startingly real and beautiful, and an admirable study of the influence and value of accidental and reflected lights.

If we had wondered and admired, as we examined the slides we have referred to, we fairly grew incredulous when we came to moonlit scenes, and at once began comparing notes as to the various possible ingenious "dodges" by which such illusions, as we deemed them to be, might be produced. There were three pictures rendering moonlight effects. One is a moonlit sea, with the play of the moonbeams on the water, so different from the flood of light thrown by the sun on a similar surface. Another is the moon itself in the midst of a mass of cumulose clouds, which are tipped with silver, and rendered more or less transparent throughout by the moon's light. The third is an interior with the figure of a lady looking out of the window, through which is seen a moonlit sky. The figure is, of course, little more than a silhouette, the edge of which is traced by a well-marked line of light. The white lace sleeve on the arm which rests upon a table underneath the window is well made out, as is also the polished surface of the table reflecting the moonlight.

That these effects of moonlight real and illusive as they seemed, were produced in some way by the aid of sunlight we felt little inclined to doubt, until on subsequently meeting Mr. Breese, and spending some pleasant hours in his company, he gave us his assurance that each view was really what it purported to be, without any trick, that the moonlit pictures were produced by moonlight only, and that they had required little more than instantaneous exposure.

Regarding the source of the extreme sensitiveness necessary in producing these pictures, Mr. Breese preserves his own secret, merely stating that it chiefly depends on a modification of the collodion he uses. A few particulars of his practice he placed at our disposal, and these will be interesting to our readers. He uses a bromo-iodized collodion, a mixture of the products of two well-known makers generally best suiting his purpose. He developes with iron, and intensifies with pyro-gallic acid and silver. He uses the silver bath, and the iron developer, with as little acid as he can to preserve cleanness in the negatives, rather looking to the conditions of harmonious relation amongst all his chemicals, than to a constant adherence to any given proportions. For intantaneous pictures he has abandoned mechanical contrivances for rapid uncovering and covering of the lens, trusting to the ready movement of his hands as more accurately carrying out the dictates of his judgment as to degree of rapidity.

The transparencies are all produced by means of wet collodion, either by camera printing or superposition, and we unhesitatingly state that the finest we have seen do not surpass them, nor in many cases equal them. They also, are developed by iron, intensified with pyro, and, sometimes toned with gold. In several cases they are printed from negatives, the sky being in one, and the landscape in another; but where this is done, the two negatives are taken in immediate succession so as to secure the same atmospheric and illuminating conditions for both. The junction in the transparencies is not perceptible.

We have not commented on Mr. Breese's instantaneous pictures of the crowded streets of Birmingham during Her Majesty's visit, and which received the royal commendation, because notwithstanding their excellence they have, perhaps, been equalled—we cannot say surpassed—by the productions of some others we have seen.

Before concluding we must refer to a question which will have arisen to the minds of most of our readers: "How is it we have not heard of these wonderful pictures before?" We can suggest but one answer. Mr. Breese is an amateur, producing his pictures for his own gratification, and that of his immediate friends; and that although a member of the Birmingham Society, he is not a talker, but, in common with many of our very best artists, finds expression in his works.

We must not omit to add a word regarding the stereoscopes manufactured by Messrs. Cutts Sutton, and Co., of Sheffield, which struck us as equal to the best we had met with. They were furnished with whole achromatic lenses of five inches focus, and produced an effect of magnitude and distance which was very fine.

THE SOLAR CAMERA.

We have some important information to communicate to those of our readers interested in the solar camera. In a recent article on the subject we referred to the doubtful validity of the patent, and to certain improvements desirable in its construction. Since that period, having given the subject some attention, we have ascertained that the patent, whether valid or worthless, no longer exists. The protection has been suffered to lapse, and the matter is now public property. Those of our readers who have felt the need of improvement in the instrument, may now produce the same instrument, or such modifications as they may choose, without any risk of infringing a patent. Competition is the general source of improvement, and we hope it will have its legitimate influence here.

We cannot but regret the serious loss which we conceive the matter must have been to the proprietor of the patent in this country; and can only suggest to him, as the best means now of retrieving any loss, that he will still undoubtedly have an opportunity of getting the start of all competitors in supplying an improved article at a reasonable price.

We shall shortly have a few words on the application of artificial light to such cameras, and the required modifications in optical and mechanical arrangements.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analylsis.

Fluoride of Silver (concluded).—Perhaps the most successful application of fluoride of silver to photographic purposes is due to Messrs. Spiller and Crookes' researches on the different methods of preserving the sensitiveness of collodion plates. In May, 1856, a paper on the above subject was published by these experimentalists, in which several new agents were proposed to effect this purpose. Processes were described in which the desired object was attained by the employment respectively of glycerine, nitrate of magnesia (first successfully used by them in 1854), the double nitrate of magnesia and ammonia, nitrate of manganese, nitrate of copper, nitrate of nickel, fluoride of silver, and the silico-fluoride of silver. The latter salts were used with the object of combining the silver salt necessary for the sensitiveness, and the deliquescent salt requisite for the preservation of moisture in one and the same compound. The two substances having these properties in the most striking degree being the fluoride and the silico-fluoride of silver, it was determined to put the idea to the test of experiment. They were prepared by dissolving freshly precipitated carbonate of silver in hydrofluoric and hydrofluosilicic acids respectively. Solutions of these salts (which are highly deliquescent) were then used in place of the ordinary nitrate bath for exciting the iodized collodion film. Plates so treated readily became coated with a layer of iodide of silver, which seemed quite as sensitive to light as if it had been prepared in the ordinary nitrate bath; and they had, moreover, the property of retaining a moist surface. Unfortunately, however, it was found that the fluoride and silico-fluoride of silver in strong solution (such as was produced upon the surface of the wet plate by spontaneous evaporation) had the property, like the nitrate, of dissolving off the precipitate iodide of silver, destroying it by forming the small holes so well known in the ordinary collodion process. Meeting with this result, they determined to try their application in a more dilute form, after exciting the plate in a preliminary nitrate of silver bath; but by this mode of treatment, also, they were unsuccessful, being unable to preserve the sensitiveness by a quantity which was sufficient to exercise a destructive influence on the film. This difficulty, added to that experienced in the preparation of the fluoride in a neutral condition, any excess of hydrofluoric acid being objectionable on account of its property of etching glass, and, on the other hand, the slightest alkaline reaction rendering it extremely difficult to obtain clear pictures on development, deterred these gentlemen from pursuing the subject further in this direction.

Cyanides.—The only cyanide of any importance to photographers is the potassium compound of this radicle. *Cyanide of potassium* can be purchased at a very reasonable rate, but it is often very impure, and sometimes so much contaminated with other salts, that it is not fit to use. The pure salt may be prepared in many ways. One of the easiest is to heat ferrocyanide of potassium in the air until it is perfectly deprived of water, which may be known by its becoming quite white, and then placing it in a cast or wrought-iron vessel, it is gently ignited out of contact with the atmosphere until no more nitrogen goes off. There is thus formed a fused mixture of cyanide of potassium and carbide of iron. When this is cool it is to be broken up and the cyanide of potassium dissolved away from the insoluble carbide of iron by dissolving it in cold water, or, if the cyanide be required very pure, in hot alcohol. The solution (aqueous or alcoholic) after filtration is to be rapidly evaporated to dryness and the resulting crystalline mass quickly placed in well-stoppered bottles, and prepared for use. If too strong a heat be applied the cyanide of potassium is resolved into nitrogen and carbide of potassium, so that the residual mass evolves hydrogen in contact with water.

The way cyanide of potassium is usually formed on the large scale is by the process known as Liebig's process. This consists in mixing intimately 8 parts of ferrocyanide of potassium, dehydrated on an iron spoon until it is commencing to slightly decompose, with three parts of pure dry carbonate of potash. The mixture is then thrown into a crucible at a low red heat, and ignited very gently until samples taken out of the fused mixture from time to time with a glass rod no longer solidify to a brown or yellow, but to a white mass. The crucible is then taken out of the fire, the mixture stirred several times with the glass rod, and after leaving the heavier portion to subside, the transparent and colourless liquid is poured from the grey spongy mass into a hot porcelain dish. The residue in the crucible may still be rendered available by exhausting it with cold water, and heating the solution with sulphide of iron. Ferrocyanide of potassium is then reproduced, and after it has crystallized out sulphide of potassium remains in the mother liquor. The carbonate of potash used in this preparation must be quite free from sulphate, which would be reduced by the cyanide of potassium to the state of sulphide of potassium. An iron crucible is preferable to an earthen one, because the latter is penetrated by the mass, and imparts silicate of potash to it. A dull red heat must be uniformly maintained during the whole process. The cyanide of potassium thus obtained forms a white mass, free from granules of iron; its aqueous solution should be transparent and colourless. The ignition must not be continued till the evolution of gas ceases, otherwise the cyanide of potassium obtained will be grey; but the crucible must be removed from the fire as soon as a sample taken out on the glass rod appears white after cooling; moreover, the deposition of the iron should be favoured by a few slight blows upon the crucible, and the upper mass, which is purer than the other, separated after slow cooling from the lower portion by means of a sharp instrument.

If cyanide of potassium is made in either of the above ways with care, it will contain no impurities of any consequence. On the large scale, however, it is scarcely ever made with a sufficient degree of care to prevent impurities creeping in. The principal of these are carbonate of potash, sulphide of potassium, sulphate of potash, chloride of potassium, silicate of potash, ferrocyanide of potassium, sulphocyanide of potassium, cyanide of potash, and formiate of potash. The former of these impurities, *carbonate of potash*, remains behind when the cyanide is dissolved in hot alcohol. This residue can be tested for carbonate of potash, by its alkaline reaction, effervescence with acids, &c. If the impure cyanide is agitated with moderately diluted cold alcohol (78 per cent.), the carbonate of potash deliquesces and forms a fluid layer at the bottom. *Sulphide of potassium* may be detected by dissolving the cyanide in water, and adding acetate of lead to the solution; a dirty-coloured precipitate will be formed instead of a white one. *Sulphate of potash* is detected by adding an excess of hydrochloric acid and then a little chloride of barium to the solution, a white precipitate will be formed if a sulphate is present. *Chloride of potassium* is detected by igniting a small portion of it with twice its weight of nitre, and ten times its weight of carbonate of potash (both of course free from chlorine) then dissolving in water, supersaturating with nitric acid and adding nitrate of silver. A white precipitate shows the presence of chlorine. *Silicate of potash* is detected by supersaturating with hydrochloric acid, evaporating to dryness, and re-dissolving in water: silica will be left behind. *Ferrocyanide of potassium* is detected by mixing the solution with a small quantity of perchloride of iron, and then with hydrochloric acid: Prussian blue will be formed. Another test is to add sulphate of copper to the solution, the precipitate upon addition of hydrochloric acid will not turn white but reddish if ferrocyanide be present. If upon the addition of the iron salt and hydrochloric acid the solution turns red instead of blue, *sulphocyanide of potassium* will be present. *Cyanate of potash* is nearly always present; it can be detected by the evolution of carbonic acid upon the addition of hydrochloric acid. *Formiate of potash* is detected by the cyanide which contains it blackening on ignition.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Historical Painting.—If history painting may be judged as history writing is judged, that art is best adapted to the aim of of the historian which most faithfully records and preserves the features of the past for the contemplation of the future. If so, let me ask what art can do this as photography can? The sculptured relics and monumental remains of departed nations, the castles or encampments of a war-loving people, the mighty temples or cathedrals of a religious race, and every scrap of evidence remaining to us of the habits, customs, appearance, and general characteristics of the past, are, even now, so faithfully cherished by this new and beautiful art, that should all such perish from the face of the earth, we should have, in its productions, a more complete and unerring record of them all than could be found in written pages or on painted canvas. As to our own and coming times, our successors will see, as in a mirror, not only the very form and features of kings, ministers, generals, and the great in every department of scientific, literary, artistic, and political labour, but the battle fields of huge victories and defeats, the growth and importance of cities, the costumes and features of successive generations, and every scene and incident of historic interest, will be placed before those eyes unborn with such truth of detail, and perfectness of representation, that history and science will wonder at its prodigal wealth of material, and poor old Time feel that his greatest power has been torn from his enfeebled grasp. If the art that does so much for us is painting, poets grow eloquent, critics grow poetical, and politicians talk grandly of the vast importance of their mighty historian and teacher, art. If the art that does all this, and does it so much better than any other art, is photography, then poets pass it by as something too common-place for the notice of their muse, critics denounce it as arrogant and presumptious in its now lowly claims, and politicians are content that it should be cooped up in the lowest department of a great National Exhibition with "railway plant," "machines and tools," "agricultural implements," "ship's tackle," "musical instruments," &c. If historical *painting* is one of the noblest branches of art, why should an art of still more important historic value be thus degraded in the eyes of the world by a nation which claims intellectual equality with the most civilized, sensible, educated, and refined of its neighbours? All honour to the Photographic Society for the energy and labour they have brought to bear upon the wrong so obstinately and stupidly persisted in by Her Majesty's palpably prejudiced and illiberal Commissioners. I trust, at least, that all our photographic societies will be prepared to lend a strong and willing hand in whatever steps the parent Society may ultimately deem it wise to take for resenting or redressing this wrong, and the correction of this absurd blunder. Surely we are not altogether powerless, with so many lovers and practitioners of our art occupying lofty and influential positions. If we want an example or leader only, is there not that royal personage, that mighty monarch, Punch, who, speaking from his throne in Fleet Street, cries, with the loud emphasis of one having power, "Ho! there, none of that, *Fair play for photography*, ye coward loons; strike one of your own size, and not a little one, only a few years old. *Don't* you hit him again, he *has* some friends!" Heaven bless your handsome humps, King Punch, and let us hear your royal voice sound like a trumpet (tooity, tooity, who said a penny one?) once again!

Horizontal Line.—This is a line indicating the height of the horizon,* which in its turn indicates the height of the camera or spectator, the line of the horizon being always on a level with the latter's eye.† Thus a bird's-eye view is one

* The participle of the Greek verb, signifying "to bound."

† If you kneel at a window commanding a view of the horizon, and mark its position on the glass and then rise, you will see the horizon rise also, still retaining exactly the level of your eye.

taken from an eminence, or height in the air*, in which the horizontal line would be nearly at the top of the picture, while, in a view supposed to be seen by a kneeling or crouching spectator it would be comparatively low. The horizontal line should never divide the picture into exact halves. a formal and unpicturesque effect being thus obtained; nor should it be too high. Experience has shown us that it's best place is at rather less than half the height of the picture. The position chosen may have a tendency to destroy the proper effect of any view intended to represent *faithfully* some given spot; for instance, suppose such a view placed in a low, level plain, with no natural eminence from which the spectator might perceive it. If the horizontal line were, in this case, placed high in the picture the general effect would certainly be falsified, and the truthfulness marred to all who could recognise the view. A low horizon helps, therefore, to convey an impression of a low-lying, flat country, while, when much higher, it tends to convey an expression of high and mountainous ground; but even in this case it should not greatly exceed in height the centre of the picture, because in that case it would too nearly approach the bird's-eye view. Objects photographed in connection with the horizon, and situated upon an elevated pedestal, say, such objects as public statues, may derive increased dignity and importance from a low horizontal line; and, frequently, by raising or lowering it, the photographer may materially improve the photographic or artistic character of his views. Even Mr. Mudd's very beautiful picture of "Coniston Falls" would certainly have been improved, had the horizontal line chanced to be somewhat lower, so as to give either more sky, or less foreground (I should certainly have preferred the former, as in so exquisite a production it is quite hard to sacrifice even the slightest portion of the view). To conclude, the expression of the horizontal line should never be overlooked; for instance, if you were photographing a dog, horse, or cow with a landscape as a background the horizon should be so judiciously placed as to convey a correct idea of the size of the animal, and indicate how much the level of the spectator's eye was above the object.

* A bird's-eye view is, strictly speaking, such a view as could only be seen from a height inaccessible to any spectator but a bird, or from a baloon.

POSITIVE PRINTING ON ALBUMENIZED PAPER.

BY M. L'ABBE' PUJO.

THE various phenomena which take place in printing photographic proofs upon albumenized paper may be traced to three principal facts, two of which are well known to photographers; the third, to my knowledge at least, has not been explained by any one.

1. Pure chloride of silver, when exposed to light, becomes coloured violet blue, and, as the reduction proceeds, the colour becomes deeper and deeper. When the action of the light is concluded there only remains a brown grey powder, which is metallic silver: to prove this, it is sufficient to take a small quantity of this powder on the tip of the finger and rub it against some hard substance, the finger and the hard body both become strongly silvered. It must, however, be remarked, that if the chloride of silver be in a thick mass, only a very thin layer on the surface will be completely reduced; immediately beneath this the chloride will be found scarcely tinged with blue; at a little further in the mass it remains quite white.

2. Nitrate of silver, crystallized, or dissolved in pure water, is not changed in the light; but upon the addition of any organic matter, such as starch, gelatine, cellulose, &c., decomposition takes place. Also, a sheet of paper impregnated with nitrate of silver becomes coloured red under the influence of light, and becomes black when the exposure is prolonged. If a piece of paper be moistened in different parts by solutions of nitrate of silver of various degrees of strength, the parts moistened with feeble solutions continue red, while the parts imbued with a solution of the strength of 15 to 30 per cent., become black, and of a green bronze metallic colour. Besides, so long as the reduction is not advanced, the hue is red everywhere.

3. If a drop of nitrate of silver be poured into a solution of albumen, or *vice versâ*, a very abundant white flocculent precipitate is immediately produced. The question arises, is this substance simply a coagulum of albumen retaining in its mass a certain quantity of nitrate of silver, which cannot be removed by prolonged washing? or is it a combination of albumen and oxide of silver? or rather, which seems most probable, is it a compound analagous to that formed by bi-chloride of mercury, under similar circumstances? I shall not now decide precisely on the intimate constitution of this body; but reserve its consideration to the sequel. Besides, the chemical composition is unimportant in the aim I propose to myself.

This compound, which I call albuminate of silver, plays a very important part in printing positive proofs. And, moreover, every normal sheet of paper passed over a salted albumen bath, imbibes a quantity of liquid which varies from 4 to 8 cubic centimètres ($67\frac{1}{2}$ to 135 minims). Now, under ordinary conditions, 5 cubic centimetres of albumen solution contain 9 grains of pure albumen, and 3 grains of salt; so that when a dry sheet of paper is placed on the silver bath, albuminate and chloride of silver are formed. about three times as much of the former as of the latter. It is therefore certain, that generally, proofs are printed on a mixture formed of choride and of albuminate, but in which the albuminate predominates; and it may be conceived that the value of a proof is intimately allied with the modifications which each of these substances is susceptible of undergoing under the influence of light. Now albuminate of silver deprived of every trace of nitrate by prolonged washing, is, when exposed to light, coloured successively, rose, red, red purple, and brown purple. The facility with which it becomes reduced is second only to chloride of silver, Besides, a sheet of paper prepared with unsalted albumen and floated on a bath of nitrate of silver, becomes covered with a coating of albuminate of silver which may be deprived of the nitrate by repeated washings with pure water. This sheet, employed in the ordinary manner for printing a positive, will give a satisfactory picture, and even complete, which, after fixing, will present red hues, with well defined contrasts between the lights and shades.

In printing, the albuminate of silver always comports itself in the same manner, whatever its mode of preparation. In the pressure-frame it becomes coloured, as already mentioned, rose, red, red purple, purple brown, and towards the end assumes a brilliant metallic colour, but still red; in the hypo bath the image becomes fainter and of a rusty red hue, but upon drying it resumes nearly exactly the red hue it possessed in the printing-frame. It is useless to pass it to the toning bath, it cannot be made to assume harmonious tones.

Without going further, I may, from the above, draw the following conclusion:—whenever an operator perceives a sheet of paper assume a red colour in the printing-frame, with a brown or brown red metallic appearance, he may boldly conclude it will tone in the gold bath with much difficulty, the cause of which being that it contains too great a proportion of albuminate of silver. Now this excess of albuminate may proceed from—

1. Employing an albumen too little salted or not at all.
2. The silver bath being too weak.
3. The paper not remaining long enough upon the silver bath.

I think it useless to explain how these three causes produce the same result.

Chloride of silver cannot yield a good positive picture, because, 1st. as the reduction takes place only upon an excessively thin layer, the blacks, after fixing, are deficient in depth; 2nd. On account of the facility with which this body is decomposed by light, the whites, if not absolutely opaque on the negative, are printed on the positive. For these two reasons the image, after fixing, will exhibit the most meagre uniformity. Among the means which admit of taking a positive upon chloride of silver alone, I shall mention the following:—Sensitize a sheet of albumenized paper on a bath of silver strongly acidulated with nitric acid, and print it in the usual manner; the nitric acid prevents the reduction of the albuminate and of the nitrate of silver. An excess of chloride of silver may be easily recognised; in the pressure-frame the edges of the paper which project beyond the negative become coloured successively, lilac, blue violet, and violet black; and when the proof is removed from the frame it exhibits upon the half-tones, and even upon the whites, a general blue violet hue.

(*To be continued.*)

ON TONING POSITIVES ON ALBUMENIZED PAPER.

BY F. MAXWELL LYTE.*

If there is any intention of preserving the prepared paper for any length of time, it will be desirable to keep it in Marion's apparatus for that purpose. Nevertheless, if the albumen employed be fresh, and the paper of good quality, the paper will keep perfectly well after being sensitized some four or five days. Care must be taken to avoid the dissemination of the vapours of ammonia or of sulphuretted hydrogen in the room where the paper is hung, else it will become discoloured. For the same reason we must avoid the emanations from stables.

The taking of positives will be regulated by the taste of the operator; always keeping in mind that the vigour of the image is always diminished after being toned and fixed. Many theories have been put forth respecting the nature and formation of positive proofs; I give the preference to that maintained by MM. Davanne and Girard, who suppose that when the sensitized paper is exposed to light, and when the compound of nitrate and chloride of silver on the surface has undergone decomposition, that the chloride of silver is reduced to the metallic state, with liberation of chlorine; that this chlorine immediately attacks the free nitrate of silver with which it comes into contact, converting it into chloride of silver, setting at liberty nitric acid and oxygen. The first is then decomposed anew, a fresh quantity of chlorine being disengaged to react again as before, while the nitric acid is decomposed, in its nascent state, by the organic matter of the paper. Thus a decomposition and a recomposition is continually going on, until no more free nitrate of silver remains, and thus several successive layers of reduced silver are formed and constitute the dark portions of the picture.

In the case where the sky has been solarized, which cannot often be avoided, it will be necessary to paint along the line of the horizon, with opaque pigment, such as vermilion or chrome yellow. After taking a proof, the sky is cut out of it along the horizon. After slightly blackening this portion of the proof by exposing it for a few minutes to the sun, it is fastened on the negative with a little gum-water. This mode of proceeding is, however, impracticable when trees rise up against the sky-line. Care must be taken not to bring the paper too near this line, for its thickness will prevent the contact of the negative and the positive during the printing, and this will render the image indefinite in this place at least. It is to avoid this inconvenience that the skies are painted. The same result may be obtained by carefully levelling the edge of the paper cut out, which forms the sky, before gluing it on.

An entirely white sky generally impairs the harmonious effect of a proof, and it is very desirable to correct this defect. This may be accomplished in three different ways. The first and best is to print the clouds photographed from nature. The second consists in imitating the clouds with cotton arranged for that object between two plates of glass; and lastly, to make a tinted sky. The same principle serves as the basis of these three plans, viz.: the application of the negatives of natural or limited clouds, and (in the case of a uniform sky) of a clean glass upon the image, and covering the rest of the proof, which is made to move up and down so as to expose that portion of the sky which is to be tinted. The card-board must be kept constantly in motion, else a harsh line will be formed across the picture, and only that part of the sky which is to be tinted must be exposed. In this way, by a little practice, excellent effects may be obtained. Observers of nature have remarked how much deeper the blue of the sky is over head, than towards the horizon. This fact must be recognized by avoiding to darken the sky near the horizon; and in this manner a most natural effect may be produced without losing many interesting details by blackening the line of the horizon in the proof.

Immediately the proof is printed, it must be placed for half an hour in running water, in order to remove the greater portion of the nitrate contained in the paper. It must then be transferred from this bath into another composed of salt and water, in which it must be allowed to remain at least a quarter of an hour, and then submitted to the toning bath, which is composed in the following manner:—

Dissolve 10 grains of chloride of gold in an ounce of water, and 3 drachms of phosphate of soda in a pint of water; add the solution of gold to the latter, and the bath is then ready for use. Almost immediately on putting the proof into this solution its colour changes, passing from its red hue acquired in the salt bath, to a violet red tint, then violet, and finally a bluish gray hue. The toning can be stopped at any desired tint by removing the proof from the solution into a dish of clean water, in which it must be freely moved about.

While the proof is in the toning bath it must be kept in motion, and frequently turned. The temperature has much influence on the toning, and the room wherein the operation is performed should be kept warm, as under these conditions a given quantity of salt performs more work. The same result may be obtained by warming the toning bath, but it loses its activity on cooling, and becomes more inactive than before.

The solutions of chloride of gold and phosphate of soda may be kept separately for an indefinite space of time without undergoing any change; but when they are mixed, they must be employed as soon as possible, for they lose much of their activity in the course of a few hours. Old toning-baths may be mixed with the old hyposulphite to be treated with the other residues.

As the formation of the precipitate of gold takes place only on the dark portions of the proof, it will be economical to trim the edges before immersion in the toning bath; the black margins may be added to the residues. After removal from the toning-bath, the proof must be washed for half-an-hour or an hour in clean water; if this be neglected the proof will change its tint on immersion in the hyposulphite bath. The water bath seems to have the effect of fixing the colour of the picture; and if it be omitted, the proof on immersion in the hyposulphite becomes spotted and stained. Other spots arising from inequalities in the albumen, invisible at first, may also be produced at this stage of operations. Strongly albumenized paper tones more slowly than that which is slightly albumenized, but the tones are richer.

This process is inapplicable to paper simply salted, for which Mr. Sutton's *sel d'or* process is best suited, or the old method of the compound hypo and gold bath.

After immersion in the water a proper time, the proof must be placed in a bath of hyposulphite of soda, of the strength of twenty per cent., to which a piece of chalk the size of a pea is added for the purpose of preventing the formation of acid, and so decomposing the hyposulphite, and producing sulphuration of the proof.

* Continued from p. 160.

The proofs must be left at least two hours in the hypo, then washed in water. Many methods have been suggested for washing the proofs so as to completely free them from hyposulphite, but I know of none better than the old method of simply removing the proofs from one vessel to another, changing the water each time. I treat all my proofs in this manner, and wash them uninterruptedly for twelve hours. This is a tedious operation, but a successful one, and I have never had a faded proof. The same result did not attend a washing of six hours.

When the proof is washed it only remains to mount it. For this object, I take a piece of card-board somewhat larger than the proof, and fasten it on with starch paste. When dried the picture is passed through a rolling-press, and then varnished with the following compound:—

White wax	60 parts.
Spirits of turpentine	60 „
Fine Copal varnish	$1\frac{3}{4}$ to $3\frac{1}{2}$ parts.

The wax is melted in a galley-pot, and, after removal from the fire, the turpentine and copal are added. The varnish is applied to the proof by means of a piece of flannel and rubbed on briskly, then with another piece of clean flannel the proof is polished.

By this means the proof is not only protected against moisture, and deteriorating gases, but albumenzied paper gains considerably in brilliancy, and the deep shadows acquire an agreeable transparency.

ON LACY'S PROCESS FOR STRENGTHENING IRON NEGATIVES.

BY FRANCIS G. ELIOT.

The very beautiful results which may be produced by Mr. Lacy's modification of a process originally proposed, I believe, by Mr. Maxwell Lyte, tempt me to record my own experience, as to the best and simplest method of securing success.

Cleaning the Glasses.—All photographers who work with bromo-iodised collodion and iron developer, know that there is not nearly the chance of being troubled with dirty glasses, as there is with simply iodised collodion and pyrogallic acid development; and that clean pictures can be taken on old glasses by the former, which would give nothing but stained negatives by the latter; nevertheless it is necessary always to clean the surface, and especially for this process, as stains will often make their appearance in the strengthening, which were not apparent before. But grease is a terrible enemy, as if not perfectly removed, so as to allow water to flow freely over the glass, the film is almost sure to rise, and crack or break away in the last washing and drying. I prefer to simply wet the glass, pour on it a little old collodion, rub well over, wash well under the tap, wipe with a clean linen cloth, and polish with a perfectly dry one; hold to the fire till quite hot, and put into a dry plate box if not to be used immediately. I have no doubt a zinc or other metal box would be preferable to wood. I never use wash-leather, silk or other polisher of animal origin.

The Collodion.—The collodion for this process must, of course, be a bromo-iodised one; but it is necessary that it should be particularly fluid and free from gelatinization, and not over thick; therefore it is better to dispense with metalic iodides and bromides, and use those with alkaline bases; ammonium, potassium, or magnesium, will answer.

The Bath.—The bath is an ordinary 35 gr. one, tested in a good dark room, until free from fogging; adding, if required, dilute nitric acid one per cent.; as it gets old it may require testing again; it may have an addition of acetate of soda, but I think it just as well without, for reasons stated under the head of developer.

Exposure.—The plate must be fully exposed, as it is sure to be hard if not exposed enough; nevertheless it must not be too long, as it is apt to flatten the middle tints too much; the right time is soon learnt after a few trials.

Developer.—The developer I prefer is a simple one of 10 grs. of protosulphate of iron, 20 mins. of acetic acid, 30 mins. of alcohol to the oz. of water, not using any acetates or citric acid, or other organic chemicals; in fact, it seems to take the mercury better if the silver is reduced as perfectly as possible, and the film adheres tighter to the glass; therefore a small quantity of nitric acid would be preferable to anything else.

Fixing.—Hypo or cyanide may be used for fixing; if the former, the plate must soak for five minutes in water after the hypo is well washed off; the plate must be well washed again and left to dry *spontaneously.* If cyanide be used it should be very weak, but hypo is better.

Strengthening.—The plate must next be held to the fire until quite hot, and then left to cool; about one-eighth inch of the collodion scraped off all round the margin, and the edge painted over with C. J. Hughes's dead black varnish. When dry the glass must now be held under the tap to wet the film all over, and a two or three grain solution of bichloride of mercury being poured into a gutta-percha dish, the glass must be quickly immersed therein; it will take from half-a-minute to a minute or longer to produce the effect required, an over-exposed plate requiring longer than an under-exposed one; the only guide is the appearance: when the contrast is not quite so strong as a pyrogallic acid negative should be, it has had enough. The colour will be a dull grey: it should not be allowed to become white. It must then be taken out and gently washed under the tap; it will not require much as the liquid is only on the surface. The next operation is to hold the plate in the left-hand, and pour on from a measure glass or lipped bottle a solution of iodide of potassium of 2 grs. to the oz. of water; the film is rapidly changed from the grey to a dirty green colour by transmitted light, which is very impervious to the actinic rays. It now only requires gently washing, and must be allowed to dry spontaneously in a good draught of air: it should not be held to the fire until dry, as it is apt to make the film peel up. As soon as it is quite dry it is best to varnish with sœhnee or other varnish as quickly as convenient, as it seems to stain by the action of the air.

Conclusion.—I have been rather minute in describing this process, as I believe it to be a most valuable one; the negatives have all the sharpness and brilliancy of albumen ones with great softness, and from the great depth and richness they give to the paper in printing, they are most applicable to the new system of alkaline gold toning.

THE ALBUMEN NEGATIVE PROCESS

As Practised by Mr. Cramb.*

After stating that he did not claim any novelty or improvement in connection with the albumen process, Mr. Cramb remarked, his sole object was to give a reliable process by which fair negatives might be secured with the minimum amount of trouble and the maximum amount of certainty.

The glass he recommended was patent plate; any method of cleaning might be adopted, so long as the cleansing was thoroughly effected. He used first, a solution of common washing soda, and afterwards, plenty of water, drying the plate on a linen cloth, and not polishing with leather. We give the details with some condensation, in Mr. Cramb's own words.

Preparation of the Albumen.—I have not in my usual practice added either honey, gum arabic, dextrine, sugar, or treacle to the albumen; and whenever I have done so by way of experiment, the result has not encouraged me to continue their use. The addition of those substances has been recommended by those whose position entitles them to consideration; but in my experience I have neither felt the necessity for their addition nor the promised advantage when I have tried them. I have always preferred the use of simple substances, as far as possible, in my photographic practice.

The whites of any kind of eggs, I presume, would do. I have tried the whites of hen eggs for the most part: new-laid

* Mr. Cramb read a somewhat lengthy paper on the albumen process, as practised by him, at the April meeting of the Photographic Society of Scotland. Our space precludes more than an abstract of the practical details of the process.

country eggs are decidedly to be preferred. Opinion has been a good deal divided among photographers on the question of whether stale albumen will do or not. My experience of a very large amount of operating in albumen, both on glass and paper, has now fully confirmed me in my first opinion, that allowing the albumen to become stale is always pernicious, though I must confess to having at times inclined strongly in favour of allowing it to decompose partially before using. The whites may be separated from the yolk in any way the operator finds most convenient. Let him be careful to keep the smallest amount of germ or yolk from passing among the whites. The quantity of albumen in which it is proposed to operate should now be *thoroughly* beaten. The addition of a small quantity of acetic acid to the albumen to make it fluid, has been recommended, and has also been the subject of some discussion. I have tried it, and find it to answer the purpose proposed.

Iodising the Albumen.—Iodide of potassium is the iodiser most usually recommended. Any iodide will do, I think, except those metallic iodides which coagulate albumen. Iodide of cadmium does so, yet it has been recommended and pictures shown which were produced with its use. In my hands the addition of some iodide of cadmium to a basin of albumen turned it into a substance resembling sour milk. Iodide of ammonium has been much recommended. Its only advantage, I think, is that it generally contains a good deal of *free iodine.*

The addition of a bromide to collodion is now pretty generally recognised as advantageous. I have always used bromide in my albumen, and have no doubt I have obtained finer pictures than I could otherwise have got. A much shorter exposure *will do*, and, above all, it materially aids in getting *thin* pictures full of half-tone. Albumen, and indeed all dry processes, are apt to give harsh pictures if care be not exercised to avoid it.

The amount of iodide and bromide to be added is an open question, much depending on the purpose to which the plates are to be applied. I have no doubt that the degree of rapidity of exposure is in proportion to the amount of iodide, if the silver bath be suited to it. That conclusion, I am aware, is not in accordance with the expressed opinions of high authorities, but it is in strict accordance with my own experience.

With plates which I wished should possess the highest degree of sensibility I have used as much as eighteen grains of iodide of potassium and twelve grains of bromide of potassium to the ounce of albumen.

The formula most usually given is about 1 per cent. of iodide of potassium or ammonium. That will do well enough, but will be slow and will give hard pictures. The addition of one-third of a bromide and a little free iodine will make it work *clean*, and give fine thin pictures. Say to each ounce of albumen—

Iodide of potassium	4 grains,
Bromide of potassium	$1\frac{1}{2}$,,

and a very little pure iodine.

Dissolve these in as little water as you can, and add little by little, shaking or beating up the albumen as you do so.

After iodising and thoroughly beating up the albumen it should stand for some time. It will generally be ready in a day, or less.

Coating of the Plates.—It has been supposed to be very difficult to get an even or uniform coating on the plate. There is no difficulty in getting such a coating of albumen once on the glass; but there is some in having the plate *dried* so as to have a dry coating of equal thickness throughout. The use of a drying-box, in which the plates are all kept quite level while drying, and are also completely protected from dust, has generally been adopted. These boxes are constructed on various plans. A convenient arrangement is to have the box made of a size suited to take in the largest glasses we generally work. The glasses slide into grooves, which are so arranged that when one glass is level all are level. It is easy adjusting the box before we begin, so that one glass is so levelled. Between each glass, and alternately with them, thin boards are inserted, which have been previously made very dry: these absorb the moisture from the plates, and so placed, the glasses will dry in a few hours. The lid or door should slide so as to cover up each groove as we put a glass in.

I would have little hope of many amateurs being disposed to have such a box made before they know if they could succeed in taking a picture at all by the process. I will give a plan which gives as good results, but is a little clumsy and inconvenient where a quantity is to be prepared. No special apparatus is required to be got, except, indeed, a simple spirit level; and that I think every landscape photographer should carry with him wherever he goes to level his camera with. We want a levelled place to put our plates on: a smooth table, levelled by wedges under the legs, will do for that. We want a cover to protect the film from dust: here, in the recess usual at the back of a common bead picture-frame, is this protector. We next require something that will absorb the moisture: the deal back of the frame exactly suits for this purpose. For small plates and great exactness a piece of waste plate-glass may be levelled on the table, on which we place the prepared glasses, and cover till dry.

Every precaution to avoid the presence of dust being taken, the operation of coating is much the same as with collodion. Pour on an abundant amount of albumen to cover the plate easily; have a small piece of paper to guide the albumen over the plate, and to remove specks of dust and air-bubbles; drain off the superfluous albumen, leaving as much on as *you want*—more or less will do, and the operator soon learns to leave a regular quantity.

The Sensitizing.—The silver bath usually recommended, and which I alone used for a long time after I began the process, is:—

Water	1 ounce,
Nitrate of silver	45 grains,
Glacial acetic acid	45 minims.

This will answer admirably for plates with any iodising up to perhaps ten grains to the ounce of albumen. It gives slow pictures, however. An albumen plate is silvered in an instant, and I am unable to say I ever observed any difference between those which were only a few seconds in the silver bath and those which were for a longer time. The flow of silver over the plate should be very rapid, the most momentary stop leaving a clear mark. A dipping bath will suit well, but a flat bath I prefer. In a dipping bath bubbles are apt to form on the surface, which mark the plate: besides, a flat bath does with a very small amount of silver solution. A bath of this description, made of gutta percha, I found to answer very well in my journey through Palestine.

For rapid plates I would recommend more silver, say sixty grains to the ounce, and not more than a sixth of the amount of acid.

After sensitizing, the prepared plates are to be thoroughly washed to remove all the nitrate of silver that will wash out. For convenience and economy of water I generally use two or six dishes. On removal from the silver bath the plate is placed in No. 1 dish, and is there kept in agitation to prevent the insoluble silver salt formed from settling on the prepared surface, till nearly all the silver is removed; it is then passed to No. 2, and so on in succession to the last; finally washing for a short time under a tap, or by pouring water from a jug. I have been in the habit of using the ordinary water of the place I am in for all operations for which water is required in this process. Distilled water would be better for some purposes; but the advantage would not be anything like a compensation for the trouble and expense of procuring it in many places.

Keeping.—The albumenised plates, if properly dried and packed away, so as to be kept from damp, will keep for any length of time.

After silvering I have never tried to keep them longer than about six weeks, and generally I am content with keeping them a far shorter time.

Exposure.—The length of time required to expose for good results in any process is a matter on which no very definite rules can be given. Albumen is generally considered slow. Personally, I believe albumen to be the quickest dry process. I have not turned my attention much to rapidity of exposure, and not at all to instantaneous exposures. I believe albumen capable of yielding instantaneous pictures with no important difference in the plan of working I generally adopt.

Development.—The development of a dry plate is an important part of the manipulation. Almost any amount of exposure can be made to yield good pictures in albumen by adapting the development to the exposure: at least as much as a difference of twelve or fifteen times can be made to yield similarly finished pictures.

Any of the usual developing agents employed in other photographic processes will answer in albumen. I almost invariably use gallic acid, which I prefer to be warm, adding a little aceto-nitrate of silver. I develop in a porcelain dish, and generally have several going on at the same time. My usual mode of procedure is something like the following:—Get a kettle of warm water, put a little gallic acid in the dish, and pour the hot water over it. My finger tells me when it is about the temperature I want. I then add the silver, mix well, then drop in the plate. If properly exposed, the picture appear in about half a minute. I attend to one picture till I see how it is going on. If it can be left I proceed to another dish, and so to a third—seldom more, except they are much under-exposed; and even in that case I cannot have a large number profitably going on, as I prefer using a fresh hot developer if under-exposed. A picture which appears in less than half-a-minute will generally be fully developed in half-an-hour. I have had fine pictures fully developed in a few minutes, and I would always prefer to err on that side. Some of the finest pictures I have ever done were about an hour in developing. I do not at this time remember having got any very fine results by long development; but yet it is a great matter if by such means one can get a picture in a case in which, without long development, there would be none. The aceto-nitrate of silver to be used in developing should contain a larger *proportion of acid* than the sensitizing bath; and it is more convenient to have it weaker—say ten or fifteen grains to the ounce.

Fixing.—The fixing is done with a solution of hyposulphite of soda, of the proportion of one of hyposulphite of soda to six of water. I prefer it generally much weaker, and not alkaline.

General Remarks.—I would yet wish to say a few words on some of the special difficulties and objections to albumen. Small holes in the film are a frequent annoyance, and arise from several causes. Imperfect beating up of the albumen produces the innumerable number of minute holes equally distributed over the whole plate. Somewhat similar effects are produced by using impure or *alkaline* iodide of potassium. The use of *free iodine* prevents this.

Dust falling on the plates in any of the various stages of the manipulation will produce holes, but quite different in character, and only here and there, over the picture. Bubbles is another of the vexations. Abundant beating assists in preventing that, and having the plate in proper season when it is silvered,—not too dry. This is not a serious trouble at all, and can be readily *cured* by avoiding the use of *alkaline* hypo. or washing waters.

I conclude with an earnest recommendation to those who hear me to try this process. Begin with one egg. Nothing peculiar is required. But determine, before you begin, that one failure will not discourage you. If I can assist in helping anyone personally over a difficulty, my services are at the command of those who will try the albumen process; and nothing will give me greater pleasure than to smooth the path for fellow-labourers in the cultivation of our art in this department.

THE PROVINCIAL SOCIETIES AND THE EXHIBITION OF 1862.

We gave in our last a copy of a letter forwarded by Dr. Diamond to the provincial Photographic Societies in reference to the position of photography in the coming International Exhibition. We are glad to believe that the steps of the parent Society are meeting with a ready response amongst photographers generally. We have received the following brief notice of the steps taken by

The Newcastle Photographic Society.

A special meeting of the council of the Newcastle-upon-Tyne and North of England Photographic Society, was held on 18th inst., G. E. Warren in the chair.

The secretary produced and read a communication from the Secretary of the London Society, inviting their attention to that portion of the Regulations of the Commissioners of the International Exhibition of 1862, which relates to the photographic art, together with the letter of the Right Honourable Sir Frederick Pollock to the Commissioners, and the subsequent correspondence, together with the letter of Professor Playfair thereunto annexed, and requesting their opinion upon the course which, in the interest of the art ought, under the circumstances therein detailed, to be pursued.

After mature deliberation the following resolution was moved, seconded, and unanimously adopted, viz.:—That the council highly approve of the steps already taken by the council of the London Society, fully concur in all their opinions, and in their entire argument in favour of a more philosophical allotment to photography in the classification of the Commissioners, and a position for specimens of its productions in the closest proximity to the group of fine arts; and with respect to the questions of the appointment of a committee and the exhibiting of photographic works, they beg respectfully to submit it in their decided judgment that neither the one nor the other ought to be done, unless the Commissioners concede the just and reasonable claims made on behalf of the photographic art, by the council, while at the same time they are prepared cordially to adopt and proceed upon whatever decision the council may see it most expedient in its wisdom finally to take.

2. It was unanimously resolved, that the warmest thanks of this council be conveyed to the council of the London Society for their highly laudable vigilance and attention to the honour and interests of the art of photography.

It was further unanimously resolved, that the above resolutions be submitted for sanction, rejection, or amendment, to the members of the society at a general meeting to be duly called by the secretary, and held in the Tower, New Bridge Street, on Friday, the 21st instant, at 8 o'clock, p.m.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 19th June, 1861.

M. Roman, of Wesserling, announces a method by which he can obtain on dry collodion pictures as rapidly as upon wet, by a slight modification of the Taupenot process, which demands an exposure six times as long as wet collodion requires. Whether M. Roman has been anticipated in his modification, I cannot venture to say, for amid the multitude of suggestions for improvements, it is scarcely possible that one may not escape the most retentive memory.

M. Roman's improvement consists, firstly, in washing the plates slightly after the first sensitizing, so as not to completely remove the free nitrate of silver. Secondly, to employ a *warm* instead of a cold developing solution. Being convinced that the plates sparingly washed in the collodion, although dry externally, are nearly in the same state as when newly sensitized, except the excess of nitrate left on the exterior of the film in the wet process, M. Roman attempted at first to make up the difference, by the use of warm pyrogallic acid in developing; the results were tolerably satisfactory, only the pictures were rather hard, and not sufficiently deep in the shadows. Attributing this defect to the absence of the *external* excess of nitrate of silver at the time of developing, he immersed the plate in a bath of aceto-nitrate of silver, and developed it with *warm* pyrogallic acid, also acidified with acetic acid. The picture then developed perfectly, in every respect equal to a proof taken upon wet collodion. To sum up the features of this modification, we say, that to obtain a proof upon dry collodion as rapidly as upon wet, wash the plate sparingly, leave upon the collodion a certain quantity of nitrate of silver (which the external dessication probably leaves slightly moist), then, after exposure, restore to it the excess of nitrate necessary for a good development, and lastly, make use of warm pyrogallic acid.

M. Van Monckhoven, who is engaged upon a course of interesting researches upon developing agents, after essaying chloride, iodide, and bromide of ethylamine he has tried with marked success, the sulphate of uranium, which he finds to be a very energetic developer, employed in the same manner as pyrogallic acid, but requiring a still shorter exposure than when sulphate of iron, is adopted. The pictures acquire extraordinary vigour, the development at first proceeds very slowly, but suddenly becomes very rapid, and, when complete, its further progress, must be stopped by immersing the collodion plate in water.

M. Kuhlmann has made some important researches upon methods for utilizing the residues obtained in the manufacture of soda. These residues have been a constant source of annoyance to the manufacturer, as they accumulate rapidly and emit fetid gases, which are a nuisance to the neighbourhood. It often happens that the masses of residues inflame spontaneously, and then, in addition to the ordinary emission of sulphurous acid, hyposulphuric acid is given off. These local combustions, which cause great elevation of temperature, become evident to the eye by a deposit of sulphur in the form of large, perfectly crystallized needles, which are formed at the orifices of the fissures where the decomposition of the hydrosulphuric acid by the sulphurous acid takes place. In the interior of the mass of residue which have remained some years in the air, cavities are found lined with magnificent crystals of a golden yellow colour, the composition of which appears to be 1 atom of sulphite of lime, 2 atoms of sulphide of calcium, and 6 atoms of water. Exposed to the atmosphere these crystals lose their yellow colour, and become bleached as their oxidation proceeds. Their crystalline form is a right rhomboidal prism, the modifications of which yields hexagonal plates with bevelled edges. To turn this class of residue to account, another is added to it, no less embarrassing; the oxide of iron, resulting from the combustion of pyrites, substituted of late for sulphur, in the manufacture of sulphuric acid, in consequence of the high price of this mineral. It was natural to conclude, if the action of oxide of iron was sufficiently energetic to burn organic bodies, that this oxide might be usefully employed to burn the sulphur of the oxysulphide of calcium and convert this latter into sulphate of lime. This conclusion was fully justified by experiment.

Equal parts of the residues of the soda vat, and of the residues of the combination of pyrites, were mixed into a paste and ground in a mill, and afterwards moulded into bricks, which become as hard as burnt clay bricks by being kept in a moist atmosphere, and ultimately become very sinorous; their colour is brown red, like ordinary pottery. When this new cement is sufficiently consolidated by remaining many months exposed to the air, although slightly porous, it resists the action of frost; and, still better, if it be mixed with a solution of silicate of potash after a certain time of consolidation in the air, and in either case, the results may be ameliorated by adding a tenth part of slaked lime to the mixture of the two residues.

Here, then, we have not only a means of getting rid of two waste products, but also of converting them into valuable materials, the applications of which are very numerous, not only to the manufacture of bricks, as explained above, but as an ingredient of concrete, for the facing of walls as a cement, for foundations of walls, &c., and for the repair of roads.

DEPTH OF FOCUS IN PICTURES.

Dear Sir,—The professors of fine art and those of science, have, unfortunately, never appeared to possess much in common.* The sage whose mind was so absorbed in seeking truth, mathematical wise, that he shook his wise head at Milton's "Paradise Lost," because it proved nothing, might have been an oracle of science, but he knew little of art. I was not altogether, therefore, so much surprised, as I might otherwise have been, to read Mr. Shadbolt's remarks at the last meeting of the parent Society, on the subject of "Depth of Focus."

A picture, *no matter how produced*, is purely a conventional affair. The representation has no object in actual relief; all its forms, dimensions, distances, and appearances are neither deceptive nor intended to deceive. Its brightest light, white paint or paper, in its utmost purity, is black compared with the sunlight of nature; and its deepest shade, a black surface reflecting light, is white compared with the perfect privation of light, &c. In short, it is the production of art and not of nature. For Mr. Shadbolt, therefore, to argue that the picture on the eye's retina, when we look stedfastly at any one object in a view, is exactly the picture the artist would desire to produce, gives the artist credit for a mistake he never could tumble into.

If Mr. Shadbolt will only try to look steadfastly at any one object for a few seconds, he will discover that even with an organ which obeys so readily the mind's slightest will, it is a task of some little difficulty, so accustomed is the eye to shift and vary its focus when looking at the objects before us. And again, when Mr. Shadbolt's eye is thus stedfastly fixed upon any one object, he will at once perceive that little beyond that one object is clearly defined, or, if he will permit me to use the term, sharp.

Now, as the eye is thus proved to instinctively and imperceptibly vary its focus so as to take in, at a glance, the full details of many more objects than could be so distinctly visible when one only was looked at; it follows that the painter or photographer has a perfect right to represent that amount of "depth of focus" which the brain, rather than the eye, takes cognizance of when we examine any natural objects upon different planes of vision; such depth of focus being really only bounded by the organization of the eye, and the presence of the atmosphere.

I would here take the liberty of suggesting to our opticians that, as lenses are to produce pictures, and not illustrations of optical peculiarities, it is rather to artists, than to those whose attainments are purely scientific, that they should look for stray hints; the art's progress being, in this respect, one with their own repute and prosperity. A lens which gave such a picture as the eye sees when looking stedfastly at any one object would, it certainly strikes me, be received with derision by both artists and photographers, as I think Mr. Shadbolt must before this have perceived.

Upon Mr. Shadbolt, as an authority in photography, I have myself looked with so much respect that, had I been less familiar with this matter, his influence might have been mischievous; and for the benefit of others with similar feelings, but who have thought less about pictures than myself, I feel bound to publish these few lines. I waited to see if anything more explanatory made its appearance in that gentleman's own excellent journal before sending these remarks, which I hope will not be either misunderstood or misrepresented, as I fear certain other remarks of mine have recently been in that gentleman's last leader.—I am, dear sir, yours truly, Alfred H. Wall.

[An article on this subject was in type for last week's issue, but left out for want of space. We cannot but think, in deference to Mr. Shadbolt's good sense, that some misapprehension of terms exists somewhere, as, without the quality in discussion, a photographic *picture* would be, if not an impossibility, at least, something even worse than a Chinese painting.—Ed.]

PICTORIAL *versus* OPTICAL FOCUS.

Dear Sir,—I find in your report of the last meeting of the Photographic Society, that Mr. Shadbolt, in a discussion on depth of focus, "*contended that it was true art to produce a picture similar to that formed on the retina of the eye.*"* It is much to be regretted that gentlemen will talk of things they certainly don't understand; and I hope you will insert the following quotation from an eminent living artist (G. Barnard), in refutation of Mr. Shadbolt's singular assertion; not that the fact stated requires any particular authority to support it beyond ordinary common sense. The quotation runs thus—(in the *elementary* instructions given to a *beginner*, remember).

"Pictures are not judged by the strict laws of optics—they are altogether conventional; in nature, we cannot look at the distance and foreground without *imperceptibly* altering the focus of the eye; neither can we look at two portions of a picture at the same moment, with attention, without altering the direction of the eye; it will, therefore, be sufficient if our studies afford us the power of giving a general appearance of reality, reserving for the most careful finish those portions of the picture intended to attract the eye of the spectator."

The next time Mr. S. so dogmatically denies "in toto" assertions proceeding from an authority, he should know something more of the facts denied * * * I hold

* I believe photography has for one of its most beautiful and promising missions the effecting of such an union.

* See last report of the Photographic Society, in which Mr. Shadbolt's remarks are in direct contradiction of our correspondent's quotation.

you culpable, and wanting in duty to your readers, my dear Sir, if this be not inserted. I forgive the non-insertion of my last remarks on this gentleman's art-blunders—but let this appear, and oblige—Yours, R. C.

[Before receiving this letter we had written an article on the same subject, in which, as regards the question in discussion, we had given expression to similar views. Mr. Shadbolt looks at the question from a scientific point of view, and having been much engaged in microscopic pursuits, regards accurate definition of objects on a mathematical plane as the chief characteristic of a perfect lens. We hold that the perfection of a lens depends on its being efficient for the work for which it is intended. If a mathematical plane only be intended to be depicted, then the lens which would most accurately define that plane would be best; but where a number of planes have to be depicted, then the lens is best which will give to each sufficient definition, each in its proper relation. If we did not insert R. C.'s former letter it was simply because we were indisposed to publish disparaging criticisms on the remarks of a gentleman who has laboured long and honourably in connection with photography, and deserves well of photographers. Although we do not entirely coincide with Mr. Shadbolt's views on the question in discussion, and think the quotation from Barnard interesting, we would rather R. C.'s letter had been conceived in a better spirit. He will perceive that the passages elided from his present letter did not add to the value of the argument, whilst they did add to its offensive tone.—Ed.]

Photographic Notes and Queries.

The Solar Camera Patent.

Sir,—Having read an article in your last Photographic News on the Solar Camera, and the various remarks on the same by several gentlemen, members of the South London Photographic Society, induces me to write for your opinion and advice. 1st. If a photographer constructs a camera for photographic purposes to work with the oxyhydrogen light, the lens being different, without reflector, is it an infringement of patent? 2nd. If the lens of the camera are altogether altered, and additions made so as to improve the solar camera, can the improvement so made protect parties that work the camera for large pictures from all law proceedings? 3rd. Can you tell me the name of any gentleman that would take an interest in the affair. I am a photographer, working for a weekly salary, and if my improvement on the solar camera is worth anything, should like to reap a little benefit thereby.—I remain yours truly, R. H. C.

[In answer to your two first questions we may state that the patent has been suffered to lapse, and is now public property, as we explain in another page. 3rd. We cannot tell you. By advertising you would be most likely to meet with such aid.—Ed.]

Ancient Camera Landscapes.

Sir,—In an old work, entitled "Graphice, or the most excellent art of Painting," printed in the year 1658, for Robert Crofts "at the Signe of the Crown in Chancery Lane, under Sergeant's Inne," I find the following, which perhaps may amuse modern sun painters:—

Page 86.—"The draught of a landskip mathematicall; they that have leasure and desire thereto, may make experiment.

"A Landskip.—Set up a little black tent in a field, made easie, portable, and convertible, as a windmill, to all quarters at pleasure; capable of no more than one man with little ease; exactly close and dark, save at one hole, an inch and half diameter, to which apply a long prospective trunck, with a convex glasse; fitted to the said hole, and the concave taken out at the other end, which extendeth unto (about) the middle of this erected tent; through which the visible radiations of all the objects without, are intermitted, falling upon a paper which is accommodated to receive them, and so trace them with your pen in their naturall appearance, turning this, your little tent round by degrees, till you have designed the whole aspect of the place. There is good use hereof in chorography; but *to make landskips hereby were too illiberall.* Surely no painter could exceed the precisenesse of these." I remain, Mr. Editor, yours truly, Exeter.

Preservative Cases.

Sir,—Is it not right that your readers should be informed of a serious defect to which "Marion's preservative cases" are liable—the spontaneous liquefaction of the "dessicating substance" used? Mine has been in use for over a year, and has acted well, until a fortnight ago, when a clammy slightly coloured liquid began to ooze out from behind the "chassis." I have already collected a wine-bottle full of it; and it is still flowing.

The liquid is a chloride; dropped into nitrate of silver, the white substance forms on the surface, and falls to the bottom of the glass in large flakes, heavily and slowly, unlike the action of salt and water dropped into a nitrate solution.

Atmosphere, or use, have had little to do with the matter; my case has been kept constantly closed, in a very dry drawer. I do not believe that more than 30 sheets of paper have been ever placed in it—they have always been thoroughly dry, for I sensitize at night, and only place the sheet in the case the next morning—after the pressure frame, too, in which I leave it for two or three hours, not to dry it, but to make it smooth and even for the plate.

"Accident" is out of question, none could possibly have occured. In fact, the great specific gravity of the liquid, about 1·360, precludes the idea of "accident."

I have found the case so useful, that I greatly regret its being liable to this defect, and only notice it in the hope that Mr. Marion may be able to devise some cure for it.—I am, sir, your obedient servant, N.

June 16th, 1861.

[It is quite clear that such a result as our correspondent describes must sooner or later be brought about in all preservative cases, as it is in virtue of the affinity for water of the dessicating agent that such cases act. The chloride of calcium, most probably used in this case, has gradually become saturated with water. In all such cases there should be facility for changing or drying the dessicating agent from time to time.—Ed.]

Want of Intensity in Fothergill Plates.

Sir,—I have been working for the past two months Mr. Sebastian Davis's collodio-albumen process (11 × 9 plates) and find difficulty, even with a liberal dose of silver in the developer, in getting a sufficiently intense negative; the details may be brought out, but there is a want of vigour or contrast. I use ——'s negative collodion. Is there any other make on the list that you think would answer better for this process?

In several negatives small spots of a light brown colour have made their appearance, in one instance before varnishing, and in the others a few days afterwards. Can you tell me the cause of these, and how to avoid them?

On the whole, the process, I think, offers many inducements to amateurs; and if you can kindly help me over the difficulties now named, it would result in my having some fair pictures for the amateur and exchange club by the close of the season.—Yours, respectfully, M. B. Joye.

Manchester, June 10th, 1861.

[We have not used Mr. S. Davis's modification for plates so large as our correspondent, but have found no difficulty in getting intensity in plates $7\frac{1}{2} \times 5$. It is quite possible that with a lens of long focus greater difficulties might be experienced. Try the final application of a solution of either tannin or gallic acid. We have tried the former on plates prepared by that process with success. The collodion, No. 2 on your list, would perhaps give you a little more intensity, but it is uncertain.—Ed.]

Colouring on Albumenized Paper.

Dear Sir,—I don't know whether any of your correspondents have tried a plan for colouring portraits on albumenized paper, which I have found very effective; it is merely to mix the ordinary moist water colours with a solution of albumen, about three ounces of water to the white of one egg.

The advantage of this plan is, that the glossy surface of the paper is not impaired, and the colour does not rub off as when dry colours are used: of course the colour must be applied quickly as it very soon dries.

I shall be glad to hear, in the next number of your journal, if you think this plan a good one.—I am, sir, yours truly, A Stranger.

15th June, 1816.

[The suggestion is certainly worth trying. We have never used the method; but it may, in many cases, be useful. The alkali in the albumen will slightly affect some tints.—Ed.]

Talk in the Studio.

The New Shakespeare Portrait is to be tested by a committee of eminent Shakespearian scholars, with a view to proving its authenticity.

The Art Department of South Kensington has given instructions for photographing the magnificent selections from the famous Campana specimens of sculpture by Michael Angelo, Donatello, Lucadella Robbia, and other eminent Italian masters.

The Guarantee Fund of the Great Exhibition has been announced at the sum of Four hundred thousand pounds.

The National Gallery has received three additional pictures by Roger Van der Weyden, Fra Giovanni Angelica, and Piero della Francesca.

Universality of Photography.—The professors of our art are acquiring a decided character for ubiquity. The *Times* correspondent, referring to the movements of the army in the quondam United States, after describing the various appendages and followers of a moving army, says: "The unfailing photographer, who may now be regarded as the pioneer of civilization, and who marches with his friendly arm to the western desert, is, of course, here," &c. &c. In a law report in the same journal we find another illustration of the universality of the profession. A witness describes himself as "a comic singer, a cigar shop-keeper, as one who let lodgings to 'professionals,' and—a photographer!"

To Colour Glass Yellow.—A very simple and efficient substitute for yellow glass may be produced by the following method:—Make a saturated solution of saffron in water, and immerse in it a plate coated with collodion precisely as with the silver bath. The collodion rapidly absorbs the orange yellow dye of the saffron, and the plate assumes the aspect of beautifully stained glass. In trying this method, for which we are indebted to Mr. Breese, of Birmingham, we macerated half a drachm of saffron in about five ounces of water, and used a thick-bodied collodion. A glass so prepared was placed over a piece of sensitized paper for half-an-hour in a diffused light without any actinic effect being produced. For a dark room or box, where sensitive collodion is used, two or three thicknesses would probably be desirable. Travelling photographers will find this a ready method of improvising yellow glass in an impromptu dark room. We commend this to the attention of those who fancy non-actinic glass is not to be had, as Mr. Breese, who works with chemicals sufficiently sensitive for the most instantaneous effects, frequently avails himself of this method of illuminating his dark room. It will be found an excellent addition to yellow glass of doubtful non-actinic character.

Dry Plate Box.—We have received from Mr. Keene, of Leamington, a specimen of his preservative non-chemical plate box for storing dry plates. It is unquestionably an admirable and ingenious contrivance, and likely to come into general use amongst dry plate photographers. That the vapours of pine produce an injurious action on sensitive dry plates, many photographers are convinced; and Mr. Keene has found that the substitution of metal for wood, whilst possessing many advantages, is also attended by at least one serious evil: small particles of metal being occasionally cut from the grooves by the sharp edges of the glass, which particles attaching themselves to the sensitive surface, and thus produce spots and comets. To meet the difficulty, this contrivance is provided. The box is of metal, but the grooves, which are formed so as not to scrape the film, are of gutta-percha. The lid is admirably contrived so as to exclude light, fitting into a groove on the outside of the box of at least an inch deep; the whole is secured by a simple but efficient fastening. Nothing better can be desired for the purpose for which it is intended.

Forbidden Photographs.—A gentleman writing to the *Times*, describing Austrian amenities on the Venetian frontier, states that after the officials had overhauled a lady's luggage and found nothing contraband, they discovered a small album of photographs, and on examining it page by page, found a portrait of Garibaldi. "With all the proper gravity of so solemn an occurrence, the detested album was laid hold of by the assembled detachment. The iniquitous portrait was extracted with due reprobation, and then condemned to the flames!"

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

To Correspondents.

*** We shall be glad if any of our subscribers or agents have one or more copies of No. 59, which is quite out of print, and we have several applications for it.

Sea-side.—Moisten the starch first with cold water, or else you will not be able to manage it at all. Use just as much cold water as will moisten the whole of the starch powder, and make it a thick paste. Unless you get it entirely moistened thus first, it will go into lumps when you add the boiling water; and if you add too much cold water at first, it will so rapidly cool the water which is added, that the proper gelatinous condition of paste will not be produced.

R. H.—The usual method of removing mastic varnish from a painting, is by friction. Slightly moisten the middle finger and proceed to rub the varnished surface gently. It will gradually abrade the surface, and the varnish will rub up and come away, leaving the painting clean. If the painting was seasoned sufficiently before varnishing there will be no difficulty; but if the varnishing followed too soon upon the painting, as in colouring photographs is too often the case, the varnish may, to some extent, have combined with the paint, and it will be difficult to remove. Varnishes may be removed by solvents, but this should only be attempted by practised hands, as there is danger of removing the paint as well.

Glasguensis.—The film drying partially when the plate has only remained a minute or little more in the camera seems to indicate that the collodion is of a very horny structure and very repellant of water. Except in excessively hot weather it ought not to dry in several minutes. Try another collodion, or add about a drop of distilled water to each ounce of the collodion you are using. We frequently allow a plate to drain a minute on blotting paper before placing it in the camera. When a plate is found to have become partially dry, from any cause, before developing, moisten the whole surface with as small a quantity of distilled water as possible, and then add that water which will have taken up the free silver which is on the plate, to the developing solution, and proceed as usual. This will prevent any risk of stains. We prefer an earthenware jar or basin for making pyroxyline. A glass bottle is rarely sufficiently wide, whilst it is too deep for convenient working. There is no objection to glass as a material, if it have been well annealed.

J. C. B.—Is thanked for his communication, which will appear shortly.

G. S. Penny.—Your communication was duly received, and either was or should have been acknowledged with thanks at the time. It will appear shortly.

William Dodson, and a Pupil of a Californian Photographer, are thanked for communications which we shall use shortly.

T. Y. Kimpton.—We have at present stock of the numbers you mention. We posted your letter. If you send us an addressed envelope, we can give you information on the subject you name.

W. W.—A coating of isinglass or gelatine is used to prevent the oil colours sinking into the photograph. It is better applied in two or three thin coatings than one thick one, as the danger of the preparation subsequently cracking and leaving the albumenized paper, is less. We have found the ordinary magilp an excellent medium for the purpose, but do not dilute the tints too much, or the picture will rapidly turn yellow and horny.

J. G. F.—The use of the rising front is to allow you to modify the relative amount of sky and landscape in your picture. You will only need to use it in special cases.

M. A.—The stains on your print arise from handling the paper after it is excited, and during the printing, with fingers not scrupulously chemically clean. Your fingers have probably been in contact with hypo solution, and only wiped, not well washed. In each one of these stains, both in front and back of your picture, there is the imprinted texture of the finger ends. By all means tone and fix separately. The muddy brown colour in the washing water before fixing should not occur; that proves that you have put fingers into it which have been in contact with hypo. You still require more vigour in your negative. The subject selected is very picturesque, and would be very fine indeed if you had a good negative of it.

H. W. Ball.—A bath ought not to need sunning, even when constantly in use, more than once in a few months if it receive fair play. Perhaps the marks on your background arise from irregular draining of the plate: possibly from over-iodized collodion; possibly from immersing the plate in the bath too soon; possibly from contact with the holder in your dark slide. We cannot say with certainty without seeing them.

F. L. R.—Your negative is evidently too weak and thin throughout. It does unquestionably as you state possess half tone, but it possesses little else, and it is just as great an evil, although not quite so common, to have nothing but half tone as to have entire absence of that quality. With such a negative a slight intensifying with pyrogallic acid and silver after fixing, would have been a great improvement, just giving that decision and crispness to the few high lights which is necessary to make the picture brilliant.

Ignoramus.—If you will send an addressed envelope, we will give you such information as we can by letter, as we cannot enter into the matter here. In answer to your two first questions, as far as we can understand them, yes.

A Rat.—It entirely depends upon the tone required as to what developer is used. As you will see from an article on another page, some of the finest transparencies we have seen are developed with iron, and intensified with pyrogallic acid. The latter generally produces a warmer tone than iron. It is difficult to copy paper prints without showing the grain of the paper, but the difficulty may be reduced to a minimum by judicious management. See report of the last North London meeting for information on the subject. Use any good bromo-iodized negative collodion. When Mr. Laws directs the use of citric acid in the usual quantities, he leaves the matter to the discretion which he naturally expects his readers to possess. No definite quantity could be properly stated as it must vary with the strength of the pyrogallic solution, the temperature, the bath, &c. As a general rule, about one grain of citric acid for every two grains of pyrogallic acid may be used; or a little more in very hot weather. Three drachms of citric acid to an ounce of developing solution must be an error, or is simply an absurdity. A little practice with the materials you have in hand will be your best guide as to the most suitable method of producing transparencies. The matter is very simple and very interesting when once set about.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 147.—June 28, 1861.

PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

As our readers are already aware, the last step taken by the Photographic Society of London regarding the question at present pending between photographers and Her Majesty's Commissioners for the International Exhibition of 1862, was to forward a circular, containing the correspondence, to each of the secretaries of the various provincial societies, and also to the representatives of the continental societies, soliciting from them an expression of opinion on this important question, so that any resolution they may lay before the Commissioners in their final reply, shall be the result of the united and deliberate opinion of the whole body of photographers both in England and abroad.

To obtain such an expression of opinion must necessarily be a work of at least a few weeks. In some cases the matter has already been brought before ordinary meetings which have met in due course since the issue of the circulars; in others, special meetings have been called; and in others, the opinion of members has been sought by letter. In the recently issued *Bulletin* of the French society we notice a full attendance is bespoken for the next meeting, in order that the matter may receive the consideration which its importance demands. The results of this universal action have not yet reached us, but we have little doubt but the general tenor of the replies will express approval of the steps taken by the Council of the Parent Society.

This being the case, we can scarcely entertain much doubt of a final issue, which shall be, at least in some degree, in accordance with the claims made by the Society. A further representation, backed by the universal opinion of photographers and photographic societies both in this country and on the Continent, will surely be sufficiently influential to induce the Commissioners to reconsider their decision and make some concessions. But in the mean time it is important to consider the alternative in case of failure. In the letter addressed to the various societies, the Council of the Photographic Society state that, as matters stand, the consideration is forced upon them, as to whether it will not be their duty to recommend those photographers "who look upon their art as more than a mechanical process to abstain altogether from exhibiting any of their works."

Now we must confess that we should look upon such an alternative, even if it could be carried out, as a most serious evil, and one much to be deprecated. That our art should be entirely unrepresented in such an exhibition would be a loss not easy to be estimated. It is true the disgrace would belong to the Commissioners, but the loss would be that of the art and its admirers. The proposal to hold, separately, an exhibition of photographs, would prove but a very inadequate substitute for a representative position in an international undertaking. Moreover, it is tolerably certain that the withholding of photographic contributions from the Exhibition of 1862 would be but partial, and that instead of an entire and dignified absence, the result would be, simply, a partial and imperfect representation of the art, the true explanation of which, would be somewhat difficult to impress properly upon the minds of the public at large.

We think, then, that these and other considerations render it somewhat important to deliberate whether, in the event of failing to obtain all that can be desired from the Commissioners, it may not be desirable to accept the separate department already offered, and appoint a Committee, in accordance with the desire of the Commissioners, who may so arrange, that the tools of our art, and the productions of its artists, shall be distinct and separate in the department under their direction. We think there are many reasons why a separate department, especially if the nominal as well as the actual classification could be modified, would be more desirable than a position wholly and entirely among the Fine Arts. Already there are indications of a feeling amongst some photographers to the effect, that whilst they are not satisfied with the proposed classification, neither would they be entirely pleased with a simple and unqualified position amongst the Fine Arts. Dr. Lockhart at the Newcastle Society contends that photography cannot be logically or philosophically called a fine art. Mr. Sebastian Davis, at the South London Meeting, contends for a representation of the present state and progress of photography as a science, which would be inadmissible in a department devoted solely to the Fine Arts. Moreover, the exhibition of photography in immediate juxta-position with paintings and engravings, might not be altogether desirable; their excellences are altogether distinct things, and we are not sure that the juxtaposition might not, in some cases, be to the disadvantage of photography, at least in the minds of many, who would not discriminate the true grounds of the respective merits of each. It is quite certain, moreover, that many photographs will be exhibited which can in no sense be regarded as works of fine art, and could merely tend to illustrate how little claim photography possesses to the position demanded for it.

If then the Commissioners could be induced to remove photography from its mechanical associations in the second section, and catalogue it in the fourth section, we think there might be positive advantages in the separate department offered. It then might be admitted that photography was a thing *sui generis*, at once a science and an art, its productions in both relations demanding a distinct consideration and representation in such an exhibition.

In expressing ourselves somewhat favourably to such a concession as accepting a separate department, we do not fear being misunderstood. Our readers will not believe us to be very ready to sink the art consideration of photography. But besides the considerations we have urged there is another element in the case to be considered. It is quite evident that the *amour propre* of the Commissioners is, to a certain extent, concerned in maintaining the position they have assumed. They may be glad to make concessions where they will obstinately resist the idea of an entire surrender of their position in the matter. We must confess we should like to know the name of the worthy to whom the brilliant idea first occurred, of placing photographs amongst patent buffers, improved switches, and the latest novelties in scaffold poles or ship's tackle. Such a classification we can scarcely conceive to have been the deliberate judgment of a body of gentlemen like her Majesty's Commissioners. The idea having been conceived, however, by some one, has been adopted by them, and they are concerned to defend it. It was Sydney Smith, if we remember rightly, who remarked that outrageous actions would often be done by men, in their corporate capacity, of which they would be ashamed individually, because "a corporation has neither a body to be kicked nor a soul to be saved." It is with a body of gentlemen acting in this corporate capacity we have to deal; and if the end desired can be gained without an entire reversal of their position, which would amount to a confession of error, then we have something to hope; but if, on the other hand, we demand a formal recantation and a complete reversal of their decision, we fear that all our efforts will be simply labour in vain.

Scientific Gossip.

Adulteration seems to set its mark upon everything employed by the photographer. Our nitrate of silver* contains nitrates of potash or lead. Our iodide of potassium is contaminated with carbonate, sulphate, or chloride; hyposulphite of soda is sometimes so adulterated with sulphate and sulphite as to be unfit for use; our pyrogallic acid contains empyreumatic oils; our sulphate of iron contains copper; our alcohol, fusil oil and water. Our ether is methylic; our chloride of gold contains almost everything but gold; our gun cotton will not dissolve; our yellow glass "warranted non-actinic" lets the light through in unwarrantable quantities (about which we shall have more to say presently); our gutta percha is a mysterious mixture of clay and mahogany dust; our nitric acid contains chlorine; the very glass on which we take our pictures "sweats" and disintegrates from excess of alkali; and now our paper is about to follow the universal law of this age of shams and adulteration. A few weeks ago some stir was made in the leading journals respecting the shameful way in which printing paper was got up abroad and sent over to this country at a price which could not be approached by the more scrupulous British maker; but whilst it was natural to suppose that adulteration would step in to swell the profits of the consumer in cases where (as in some of the cheap weekly journals) a difference in price of one farthing per pound is equal to some thousands a year profit or loss, photographers have a right to fair treatment when they are willing to pay a comparatively high price for what they use. But it seems that human nature, or at least the commercial development of it, is incapable of resisting the chance of increased profits, and we are sorry to find that our photographic paper is now gradually being nibbled at. Complaints have for some time past been made to us of the inferior quality of paper, especially the cheap foreign varieties now in the photographic market. They would not tone, they spoilt the baths, and altogether acted in a way which the users of good paper were unaccustomed to. To casual observation these papers presented nothing remarkable. They have a considerable degree of hardness and opacity, and in that respect contrast favourably with some papers which are in reality of first rate quality; for a pure paper made from the best descriptions of linen or cotton rags, and well-sized with gelatine and a little alum, or with starch, &c., as frequently employed in foreign mills, has a semi-transparent appearance similar to parchment. Of this class are the kinds used for the manufacture of bank notes and the so-called "loan paper;" which have extraordinary power of resisting the wear and tear of rough usage. For some time past it has been the custom to increase the body of such paper by the introduction of a small portion of kaolin into the pulp; in fact, most of the cream laid writing paper owes its beauty to this or similar admixture; and when the proportion employed is limited to the amount necessary to counteract the transparency of a pure linen fabric, and the mineral matter is no more injurious than pure kaolin, we should consider that such an admixture was quite as legitimate an ingredient in the manufacture of paper for photographic purposes as the alum employed in its size. Rags, however, are dear, and are likely to be dearer still before long, whilst clay is always to be had for the digging, and manufacturers have consequently kept on adding more and more of the mineral constituent until it has become so excessive as not only to be an adulteration, but also to affect very considerably the beauty of the positive print. Fortunately, the photographer can readily test the quality of paper in this respect. He has only to burn a piece of it slowly, and notice the ash which it leaves. Good paper (of which that commonly known as "Swedish filtering," made by Munktell, may be taken as the type), leaves a scarcely appreciable amount of ash on burning, and this is so light and feathery that a breath blows it away. Clayed paper, on the contrary, leaves a grey friable residue, having the form and apparently the texture of the original paper, and consisting almost entirely of clay. We have here described extreme cases in each instance. Probably no photographic paper could be made as pure as Munktell's unsized paper; whilst it is not likely that such an extreme case as a 33 per cent. adulteration will come in the photographer's way, and spoil his baths for a long time; but the evil is creeping on, and should at once be stopped. The actual amount of clayey matters, added to the pulp, can be readily ascertained. Weigh out 100 grains of paper, and burn it in a thin porcelain crucible, or platinum dish, until the ash is white or at most grey, no black carbon remaining unconsumed; then weigh the whole and subtract the weight of the crucible (previously ascertained) from the joint weight of crucible and ash. The ordinary scales in common use will be quite accurate enough if they will turn to half a grain. If the 100 grains of paper were Swedish filtering paper the ash would not weigh enough to be sensible, whilst in a heavily adulterated paper the amount left might be as much as 33⅓ grains, or one-third the weight of the paper taken. As we said above, if pure china clay were the only mineral employed, and it were not present to a greater extent than five per cent. (or even a trifle more, if the paper were good in other respects), it might be considered a legitimate constituent; but photographers ought to make an energetic protest against a higher per centage than this, for several reasons. It is an adulteration of an inferior for a valuable article; it communicates brittleness of structure and rottenness when wetted, the heavy mineral matter tending to disintegrate the fibre when undergoing prolonged washing; and the clay present not taking the salt and silver solutions so well as the linen fabric, gives a woolly granular appearance to the positive, which is also wanting in vigour. The most serious fault, however, of kaolin in paper is this: it is well known that this earth has the property of absorbing colouring matters with extraordinary avidity, and it is on this account that photographers use it to remove the colouring matter which gradually accumulates in the positive bath in which albumenized sheets have been excited. Now what holds good in the case of free kaolin is likewise observable when it is mechanically intermixed with linen fibre; if the positive bath is in the slightest degree discoloured, the kaolin in the paper exerts its affinity for it, and the certain consequence is that the white parts of the picture suffer in purity. Even if a perfectly colourless and new bath be employed, the same thing is likely to occur. There is always a certain reaction between the silver and the matter used as a size (albumen, gelatine, &c.). In ordinary cases, the slight darkening produced by this cause washes off in the different baths; but if kaolin be present, it will be firmly fixed in the paper, and injure the brilliancy of the picture.

If such are the evils of pure kaolin, they are even worse when other bodies are employed. Plaster of Paris, from its slight solubility in water would, in addition to its mechanical objections, have a chemical action upon the various baths which cannot fail to be injurious, whilst, if inferior kinds of clay are used, they would have all the ill effects of china clay with that of their own bad colour superadded.

* We are of course referring to cheap, unauthenticated materials. The photographer can generally make sure of getting what he wants free from adulteration by going to a good house and paying a fair price.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Idealizing.—By this term we convey the impression of an art creation, which, taking nature for its model, yet so combines the various excellencies and beauties of the many in the one, that the production is recognised as something apart from, or superior to, nature. Certain modern artists have, however, so degraded the meaning of this term that even the mere mechanical enlargement of eyes, straightening of noses, pursing up of lips, together with the unnatural ludicrous diminishment of the hands and feet have been dignified under the term *idealizing* to the exclusion of higher and far worthier aspirations. An elevated conception wrought out harmoniously in all its features and details, although in perfect accordance with the truths of nature, will be said to be *idealized*, and a perfect, or very nearly perfect model (such may occasionally be discovered) would, even if executed with the fidelity of a photograph, be termed *ideal*, that is to say, *if painted*, for I do believe that were it possible to discover a living fac-simile of the Medicean Venus, and photograph the same, your bat of an art critic would, just now, see nothing in the picture but repulsive indelicacy and ugliness, and would turn from the same with virtuous indignation to contemplate with rapturous expressions some such scene as that recently painted by ———, in which the half-naked and voluptuous forms of a group of charming female models are associated which suggestions which I am positively afraid to refer to more definitely.

Imaginary.—The education of the imagination is one of the artist's chief duties, and should be refined and cultivated with untiring care and study. The picture should live in the imagination long before it is executed by the hand. Rejlander looked about for his model of John the Baptist for nearly twelve months, and when he did meet a gentleman whose head resembled that he was in search of, he never met him without seeing his head on a charger instead of the shoulders it rightfully belonged to; therefore, I do think, that had I described this photograph of Rejlander's as an imaginary subject, I should not have been far from the actual truth. The imagination is the eye of the mind, with which, when darkness has closed up the outer sight, we still see. But it is only when the fancy has the power of creating that the "mind's eye" has the power of seeing, and this creative power is always more or less the result of education and cultivation. I therefore look upon the neglect of such a quality as something positively criminal, tending, as it does, to destroy one of the most beautiful of that great, good Creator's loving gifts to man: for as we lose our limbs when they are kept continually inactive, so do we lose our mental organs from the same degrading cause. Thinking thus, I grow fretfully impatient when owlish, old-fashioned folks denounce all works of imagination, and think there are no poems worth the reading but those in their hymn-books, and no facts save such as are to be discovered in histories biographies, and newspapers. What can such know of of poems or paintings, and how can such hope, when they take up photography, ever to produce works of art. If you would become an artist—no matter through what medium—you must not neglect the imagination. There are those who will endeavour to persuade you that such imaginations as our great works of art display, are traceable purely to intuitive genius, which is a special gift only vouchsafed to the elected few. I don't believe them. Such reasoning had its origin in a mere excuse for laziness, or for shirking the tedious plodding toil of beginning at the beginning. Of course the chances to which we owe the thing called genius are rare; but as the world progresses they will become less so, and then such artists as were once known when the imagination was the most cultivated portion of the mind (cultivated at the expense of every other organ by that priestcraft which so well knew the power of superstition as created out of the imagination) will be as plentiful as ever.

Imitation.—Not even "sharpness" has been so great a source of mystification and controversy among photographers as "imitation" has been among painters and fine-art writers. How far, and to what end it is to be carried, and what method is best for its attainment, are questions continually exciting discussion. Some enthusiasts, in the egotism of their love, almost seem to fear lest the power of the *artist-man* should soar to a level with that of the ARTIST-GOD; and looking, not upon the miserable inefficiency of their petty means, or the presumptious folly of their vain ambition, they cry aloud to the aspiring artist, "Stop! stop! lest you should render your imitations no longer *art*, but *nature!*" This question is intimately associated with that of the position photography may claim as a fine art. If, as some assert, the loftier qualities of art can be discovered in the scenes of nature, or, as Sir T. Brown says, in "the art of God," then, any art, sufficiently imitative, may reproduce such in its works. If, on the other side, as is also asserted, art *alone* originates such qualities: it then remains to be seen whether photography does not possess sufficient control over its imitative resources to produce similar effects. My own opinion, as frequently given in former articles, is too well known to my readers to need repeating here, and the real solution of the question will be found rather in our works as photographers than our works as writers. Art was undoubtedly given by the Great Creator of the universe to develop the nobler aspirings of the human mind; and that art which can accomplish this has always been regarded as the loftiest and the best. The rules of art should rather be regarded not as beauties chosen for so adorning and perfecting its productions that nature may thereby be *surpassed*, but rather as crutches for its support and assistance. Such rules should teach him the folly of merely imitating the inimitable; of halting and limping so very, *very* far after nature, and all the time, ludicrously enough, pretending to be running a race with her for perfection, should show him that while he chronicles the scenes about him as faithfully as his little means will permit, and makes the most of them the while, he should so blend therewith the records of human thoughts, as expressed in the spiritual utterances of nature, that his poor imitation may "snatch a grace beyond the reach of art," and claim a far nobler mission than even the utmost perfection of mere imitation.*

A curious distinction has been upheld by the poet Coleridge, the painter Fuseli, and very many other eminent men, both artists, poets, and critics, between imitation and copying. Imitation being said to be perfectly legitimate, and copying exactly the reverse. The meaning of such assertions is very easily perceived perhaps, unless you insist upon taking the two words for exactly what they are worth in the dictionary; but such novel definitions do little beyond rendering confusion more confused. Copying is regarded by these eminent individuals as the mere *mechanical* means, while imitation, which certainly demands the *intellectual* agency of art, as well as the mechanical, may be regarded as being, in reference to art of course, something beyond mere copying. These writers, however, are frequently quoted as evidence against photography as a fine art by those who think the imitation of a photograph is of the kind implied by this use of the term copying.

Much confusion, again, has been generated by writers who have regarded deception as the end of imitation, forgetting that from the very nature of our materials deception must be, in any case, a positive impossibility. It is true that we hear the ancient painters praised because their works were so natural that birds and beasts even were deceived by them; but I have yet to learn that birds and beasts are particularly acute judges in these matters. Certainly, I have seen birds alarmed in mid-day at an old coat and hat on a stick, which formed about as miserable an imitation of humanity as could well be invented, when I knew well enough that if one of Sir Joshua's most forcibly delineated and natural portraits were laid face uppermost in a field, these same saucy little warblers would have hopped as impertinently and fearlessly over eyes, nose, and mouth, as if the canvass had not the most remote appearance of humanity in any one of its numerous appearances. When, therefore, I read authors who denounce imitation because it may lead to deception, I regard the ghost they thus create with a smile as a mere bogie for frightening children, or an ingenious excuse for those who shrink in laziness or cowardice from rendering nature as she is, turning with affected disdain from the real to some mean con-

* It must not be supposed that I denounce imitation, but I merely urge the importance of art's higher aims.

ception of their own, which they foolishly term ideal. You would not attempt to walk through the frame of a picture into the scene depicted, nor would you recognise the sculptured Venus for anything but marble; the chalk drawing is, at the slightest glance, palpably chalk, and the camera picture's first impression conveys the fact that it is neither more nor less than a photograph, in short, deceptive. Imitation can hardly exist in connection with any one branch of imitative art, and there is no reason why we should desire that it should.

INSTANTANEOUS COLLODIO-ALBUMEN PROCESS.

The particulars of a highly interesting dry process have recently been published in Paris, by which. it is stated, pictures may be produced with as short exposures as are necessary in the wet collodion process. The details are published in a pamphlet by M. Chevalier, and we have for the last few weeks been hoping to procure a copy, but have not yet received it. As a brief allusion is made to the process in the letter of our Paris correspondent last week, and our readers may be anxious to hear something more of the matter, we avail ourselves of the kind permission of our good friend Mr. Sutton, to make use of the abstract of the process which he issued in a recent number of the *Notes*, the copy of the pamphlet from which it was taken having only been lent to him for a few days, he was unable to place it at our disposal. Mr. Sutton describes the matter as follows :—

"M. Arthur Chevalier, optician at Paris (son and successor of the late Charles Chevalier), has just published a pamphlet the title of which will put every one of our readers on the *qui vive*, and fill him with impatience to know more of its contents, or they are not the enthusiasts we take them to be. The title of this pamphlet is 'Photographie ;— Lettre à M. Arthur Chevalier concernant un procédé sur collodion sec aussi rapide que le collodion humide ; par Mons. G. Roman, de Wesserling.' That is to say, M. Roman has communicated, in a letter to M. Chevalier, the particulars of a dry collodion process which is as sensitive as the wet one; and this letter is published in the pamphlet alluded to, and can be obtained from M. Chevalier, No. 158, Palais Royal, Paris.

"In the preface, M. Chevalier says, 'I have seen the last proofs by M. Roman. The delicacy of his landscapes leaves nothing to be desired, and his portraits upon dry collodion are as soft and fine as those taken by the wet process. This is a very important step, and one which will attract to photography all those who have hitherto been afraid of the necessity of preparing their plates at the time of using them.'

"Now for the process itself. But first let us remark that the tone of M. Roman's letter conveys the idea of perfect truthfulness and frankness. There is entire freedom from exaggeration. He gives his *reasons* for what he recommends,—which is so rarely done by writers on photography. He writes with the feeling of a man who understands and appreciates a fine negative; and he enumerates the hundred little cares which the experienced practical photographer so well knows to be essential to a high order of succees. We are much pleased with M. Roman, and put faith in what he says, because he appears to write honestly from his own large practical experience.

"M. Roman's rapid dry process is simply a modification of that of Dr. Taupenot,—and it consists in not thoroughly removing the whole of the free nitrate in the last washing; —and developing with *hot* pyrogallic acid. In his concluding remarks he positively affirms, 'not only are my dry plates as sensitive as those prepared with wet collodion,— they are even *more* sensitive.'

"We cannot, of course, translate the entire pamphlet, but the following indications of the process will be sufficient guide to those who wish to know something about it, and to give it a trial.

"The plate is collodionized, excited, and washed as usual, in Taupenot's process; then bromo-iodized albumen is poured over it, and it is dried and put away until ready for use. The bromo-iodized albumen is composed thus :—

Albumen	110 grammes.
Water	50 ,,
Iodide of ammonium	$\frac{1}{2}$,,
Bromide of ditto	$\frac{1}{4}$,,

"This is beaten up in the usual way, and to the liquid, when settled and decanted, are added 3 grammes of ammonia.

"These dried plates are insensitive to light, but they should be prepared in the dark room, and not in daylight. In order to excite them proceed thus :—

"Immerse the plate for 30 or 40 seconds in a bath of aceto-nitrate, made thus, and always cleared with kaolin :—

Nitrate of silver	8 grammes.
Glacial acetic acid	8 ,,
Water	100 cubic centimètres.

"On its removal from the bath the excess of liquid is allowed to run off, but not till it does so in drops, and the plate is then put into a dish of water, and afterwards into a second. This is all the washing it is to have, and it may now be put away for use in the camera within 36 hours; that is from the morning of one day to the evening of the next. Within that time the film of collodion does not become thoroughly dry, and the plate retains its sensitiveness unimpaired.

"The exposure is the same as for wet collodion, and the image is developed in the following way with *hot* pyrogallic acid :—

"The plate is first dipped into the last exciting bath of aceto-nitrate, and left there for half-a-minute. The back is then wiped with blotting-paper, and the plate put film upwards into a bath of pyro, heated to about 120°. The proportions of this bath are :—

Water	100 grammes.
Pyrogallic acid	$\frac{1}{2}$,,
Glacial acetic acid	10 ,,

"The image appears immediately, and as soon as all the details are fully indicated the plate is removed from this hot bath,—washed,—slightly rubbed with cotton wool to clean the image from deposit,—and then put into a fresh cold bath of pyrogallic with a few drops of silver added. The image becomes now rapidly intense. No heed need be taken of stains, because these can be rubbed off after the picture is fixed. The entire development occupies about 10 minutes, and the picture is then fixed and finished in the usual way.

"Such is M. Roman's sensitive dry process."

POSITIVE PRINTING ON ALBUMENIZED PAPER.

BY M. L'ABBE' PUJO.*

Albuminate of silver yields an image with well-marked contrasts, rather hard even : the chloride, on the contrary, a picture which may be pronounced as too uniform, or flat. Therefore, in varying the proportions of these two elements, by employing simply albumen more or less salted, or a paper more or less porous, the operator can obtain at will any effect he may desire. But this will not be sufficient : the positive proof must also present another quality; it must be in good condition for toning. Now, every photographer has remarked, 1st, that a proof that always remains red or brown, and becomes of a red metallic colour, never tones well ; 2nd, a proof tones well when on removal from the pressure-frame, the blacks are of a green bronze metallic colour ; the toning being much more rapid and beautiful as the metallization is more advanced and greener in hue.

* Continued from p. 292.

This is but a consequence of a fact, which I shall now explain, *i. e.*, the toning consists of a precipitation of gold from the bath by the metallic silver which forms the image, a precipitation similar to that which takes place in the same bath when the image, instead of being formed of molecules of silver, is formed of molecules of copper or of zinc; only the silver, which belongs to the same section as the gold, can only precipitate the latter metal slowly and with great difficulty. This established, we may easily comprehend that the more molecules of metallic silver there are upon a given point of the positive, the more prompt and abundant the gilding (toning) will be. To obtain a good toning consists, therefore, of accumulating as much metallic silver as possible in the reductions which form the image. And this is the part the nitrate of silver plays.

A sheet of paper imbued with nitrate of silver only, will give an image; but it requires two whole days exposure in the sun; while, in the presence of chloride and albuminate of silver, the reduction of the nitrate of silver proceeds more quickly, and shows itself in a bronze-green metallization on the edges of the paper which project beyond the negative. The proportion of nitrate must not, however, be unreasonably increased in the positive baths. Too large a quantity of this salt remaining on the proof either maintains the paper in a constant state of moisture, the image being then of a uniform blue or grey tone, or in the crystallizing it will break up the surface aud produce a multitude of holes, and destroy the negative also. If the quantity of nitrate cannot be conveniently reduced below 20 per cent., it ought not to exceed 40 per cent.

A proof when taken from the printiug-frame is formed of three super-imposed images, the first furnished by the albuminate, the second by the chlorides, and the third by the nitrate of silver. The albuminate and the chloride, in well chosen proportions, give the true relations of light and shade. The nitrate of silver, in reducing itself with facility by the presence of the chloride and the albuminate, accumulates metallic silver everywhere where reduction takes place, and thus powerfully contributes to supply the element necessary to touing.

I shall notice, *en passant*, a fact which explains why positive paper keeps without deterioration in boxes with chloride of calcium. A sheet of paper, sensitized in the ordinary manner, was freed from the nitrate of silver by repeated washings in pure water, and put into a tightly closed box. After the lapse of several months it still retained its primitive whiteness. (This single experiment will require to be repeated to be confirmed.) From this it results that the deterioration of positive papers is due to the chauge in the nitrate alone; and as the reduction of the nitrate can take place only in presence of moisture, there are ouly two means of preserving the paper, either by removing the nitrate, or by keeping the paper in a state of absolute dryness. In selecting the latter, the best selection has been made, because the nitrate is necessary to the production of a good image.

ON TONING.—No toning bath can be compared with that of chloride of gold, for beauty and variety of hues, and especially with respect to permanence of the proof. In this bath the proof becomes covered with a protective coating of the most unoxydizable of the metals; for a proof properly toned will not completely disappear in boiling nitric acid, and a silver button, which I had every reason to suppose exempt from admixture of foreign metals, immersed in this bath for 48 hours, became covered with a metallic coating presenting the colour and brilliancy of gold, which resisted the oxydizing flame of the blow-pipe.

This bath may be employed before or after fixing. Employed before it may sulphurise the proof, unless the process indicated by Mr. Maxwell Lyte be adopted. In fact, the least trace of acid from the decomposition of the nitrate suffices to set the sulphur free. I prefer to fix the proof first, and afterwards immerse it in a toning bath composed as follows :—

Water	35	ounces,
Hyposulphite of soda	3½	,,
Chloride of sodium	2½	,,
Chloride of gold	30	grains.

If the addition of the chloride of gold causes a precipitate of sulphur to appear, the bath must be left several days to settle, then carefully decanted and filtered.

Every proof after six hours immersion in this bath should have its bronzed metallic blacks of a fine, velvety, black colour. To make the light lilac hue disappear which sometimes covers the half-tones, it is sufficient to pass the proof into a bath of cyanide of potassium of the strength of one per cent., which causes all the proofs to become blue black in a few seconds.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society was held on the evening of Thursday, the 20th inst., at St. Peter's School Rooms, Walworth Road. The Rev. F. F. STATHAM, A.M., F.R.S., in the chair.

After the usual routine proceedings tho Secretary read the report of the Committee. (See p. 305.)

Mr. S. FRY had pleasure in proposing the report be received and adopted. Regarding a subject referred to in tho report, in connection with which his name was mentioned—a process for dispeusing with the silver bath—he wished to observe that he had withdrawn from all councctiou with it. The discovery was Captain Dixon's, and it now rested solely in his hands.

Mr. BORCHERT asked if tho process were really likely to supersede the method of operations at present in use.

Mr. FRY scarcely liked to give an opinion. The process undoubtedly possessed great promise. Mr. Simpson, the editor of the PHOTOGRAPHIC NEWS, had both seen some of the pictures produced by it, and had himself produced some. Tho process had sufficient promise to induco him at one timo to believe a complete revolution in the practice of collodion photography was not improbablo. He still believed the process was capable of doing much; but how far, under existing circumstances, it was likely to be carried out, he should not like to say.

Mr. FITCH seconded the adoption of the report, which was carried.

Mr. HOWARD remarkod, if anything were needed to give emphasis and effect to somo of tho propositions in tho report, perhaps the reading of the Treasurer's statement of accounts would add that, for it would be seen there was really a deficiency of £3 16s. This arose partly from the preliminary expenses incidental to the commencement of any society, and partly from other causes; the amount was not serious, and might easily be distributed over two or threo years for payment. After a mature consideration of the subject, tho Committee had come to tho conclusion that it was much better for the Society to cease to supply, or identify itself with, any Journal, aud loavo each member to subscribe to such as as he might choose. Tho Treasurer's accounts, which had been examined and found correct, stood as follows :—

RECEIPTS.		EXPENDITURE.	
Subscriptions ...	£26 18 6	Various Expenses ...	£31 4 8
Cash in hand June 1860 ...	1 0 1		
Balance due to Treasurer	3 16 0		
Total ...	£31 4 7	Total ...	£31 4 8

There were still some liabilities outstanding for school-room, gas, &c.; but there were also subscriptious outstanding to the amount of £3 8s. 6d.

The CHAIRMAN suggested that it would be a much more satisfactory arrangement of the small deficiency existing could it be made up at once by each member contributing a small sum. This was done, and a sum of about £2 raised in a few minutes, leaving the deficiency merely nominal.

The CHAIRMAN was unwilling that this portion of the business should be concluded without proposiug a vote of thanks to their excellent Secretary. Much of the success of the Society he was sure, was due to the untiring energy and enthusiastic interest of Mr. Wall; the consequeuce was that the members generally, without any trouble to themselves, were certain to find something interesting and instructive provided at each meeting during the session.

Mr. Howard, in seconding the motion said, none knew so well as himself, and the Committee generally, how much the success of the Society depended on the constant and never-flagging exertion, in its behalf, of Mr. Wall; whoever else failed, he was always at his post.

The vote was carried by acclamation, as were also votes of thanks to the President and Treasurer.

The ballotting papers were then called in, and the following gentlemen were announced as unanimously elected officers for the ensuing year:—

President.—The Rev. F. F. Statham, A.M., F.G.S.

Vice-Presidents.—Sebastian Davis, G. Wharton Simpson, C. Jabez Hughes.

Treasurer.—F. Howard, 12, Whittingham Villas, Studley Road, Stockwell.

Honorary Secretary.—A. H. Wall, 11, The Terrace, Walworth.

Committee.—Messrs. Hannaford, Fry, Leake, jun., W. Clark, Fitch, Quentery, Borchert, Foxlee.

The Chairman then called the attention to a letter from Dr. Diamond as Secretary of the Photographic Society of London, and pointed out the anomalous position in which it was proposed to place photography in the International Exhibition of 1862. (See below.)

The subject of the out-door meetings of the Society was next taken into consideration, and it was finally agreed that as the meetings of the society will in future be held on the second Thursday in the month, the out-door meetings were to be held on the second Saturday in the month. The appointed *rendezvous* for the first meeting is West Croydon Railway Station at 2 o'clock, p.m., on the 13th of July, thence to proceed to Beddington Park. Should the weather on that day prove unfavourable, the meeting will be held ou the 20th.

The proceedings then terminated.

THE SOCIETIES AND THE INTERNATIONAL EXHIBITION.

South London Society.

At the ordinary meeting of this Society, held on the 20th inst., the Rev. F. F. Statham, A.M., F.R.S., in the chair, the subject of the proposed classification of photography in the International Exhibition, was brought under attention.

The Chairman, after calling attention to the anomalous classification proposed, thougbt it was important that the various societies should endeavour, by a united expression of opinion on the subject, to induce the Commissioners to reconsider their decision on the subject.

The Secretary read some portions of the correspondence on the subject, with which our readers are already familiar. He then proceeded to say:—The question to which our attention is called appears to be somewhat complicated. That photographers who live by their professiou *will* exhibit their works at the forthcoming National Exhibition cannot be doubted. Applications for space have been already made, and preparations are being carried on for such purpose by most of our best men. Photographic societies are powerless to prevent this, and as a matter of business alone it is too important to professional men for us to expect that they will neglect their own personal interests for the sake of advaucing their art in public estimation. Nor, it may be reasoned, while the absence of photographic productions would not tend to remedy the mischievous tendency of this strange arrangement of Her Majesty's Commissioners, the presence of first-class photographic pictures would certainly tend to show the world how little the art deserved the degradation it had been forced to submit to. From one of the letters I have read, it will be perceived that certain concessions have been made, inasmuch as we find that they state that there is nothing to prevent photography being placed in a separate room, or in juxtaposition with engravings, or any other analogous and suitable class of objects. To such au arrangement there cannot be any very great objection I should think. But next comes the great bug-bear and difficulty. The commissioners seem willing to give us the half-pence we solicit, but we must also take the kicks which accompany them. In other words, photography must not claim a more important position than that accorded to its apparatus. Well, what is to be done, or, rather, what *can* be done? If the council of the Photographic Society refuse to appoint a Committee to look after the interests of the art, and see that it is fairly represented by the productions exhibited, it is not at all unlikely that a crowd of photographs will appear in the Great Exhibition of next year which will *really* be more fairly the productions of lenses and cameras, than heads and hands; and the art, in consequence, may receive so serious a blow, that its advancement in public estimation, and its consequent progress as a branch of pictorial art, will be thrown back for very many years to come. The occasion is, indeed, a most important one, and, as a society, we shall not do our duty if it does not receive serious consideration. I therefore call upon you, gentlemen, to give the officers you have elected such aid in drawing up a reply to Dr. Diamond's letter as may enable them to represent well and truly the opinions of the members generally, in reference to the matter in dispute. I should be very sorry to see our beautiful art degraded to the level of machiuery and apparatus. I should be just as sorry to see it unrepresented next year, and still more sorry if it should be unfairly represented. However, I do think that by appointing the Committee requested by Her Majesty's Commissioners the Photographic Society would be in a better position to urge and enforce the claims of the art, although if we *do* take the kicks with the half-pence, we should at least protest against the former as being perfectly undeserved, and emanating purely from gross ignorance and obstinate bigotry. Before concluding I will just add that photographs are not yet strong enough, *as works of art*, to compete with the professional painter, or first class engraver, and this would only be made too apparent to those who would overlook the infantine coudition of the art, and the want of art-education in the photographer, and saddle all faults of the individual on the back of photography. Of course, there are many photographs—I am proud and happy to say, *very many*—which as pictures even could not be surpassed by the productions of any artist, but these are rather the exceptions than the rule at present, although we have excellent indications in the present condition of artistic photography from which to augur "a good time coming."

Mr. Sebastian Davis said: Although cordially agreeing with the general protest that has arisen from the photographic world against the attempt to lower the position of its artistic productions from their rank as works of art, I must at the same time call attention to the necessity of recognizing the distinct interest attached to many pictures intended solely to illustrate the principles involved in their production. It is in consequence of overlooking this distinction that many persons are apt to pronounce an unjust sentence upon the artistic capabilities of photography, and to pass a deprecatory estimate upon the art itself. They disregard the fact that a photograph may possess an intrinsic value apart from any pretensions to pictorial excellence. It frequently happens, moreover, that the photographer is called upon to delineate objects of great interest with an accuracy and fidelity at variance with the exercise of artistic skill. The representatiou, for instance, of an event of public importance, the opening of any national building, the arrangements for carrying out any great engineering project, the registration of meteorological or electrical changes, would be most valuable records of a passing event, without necessarily having any pretensions to rank as a work of art. But although wanting in the latter respect, such a record or records could not justly be regarded as the mere offspring of mechanical arrangements, nor as devoid of the power of awakening intellectual pleasure. To promote, therefore, a correct appreciation of the full scope of the powers of photography in the public mind, I advocate the recognition and classification of photography generally under the two distinct heads of "Art-Photography," and "General or Applied Photography." It appears to me that by impressing the public mind with an understanding of the existence of this two-fold feature of our art, art-photographs would be estimated according to their true value as works of art, and that this estimation would act as a stimulant to make them increasingly more so. General or applied photography would then upon the other hand be valued as possessing merits peculiar to itself, and be regarded in its special character as a valuable adjunct in the promotion of scientific typographical, and industrial advancement. The estimatiou of a photograph, even in the latter point of view, has no right to be reckoned as a mere mechanical performance; it is a scientific production dependent for its existeuce upon the discoveries that have arisen from the exercise of mathematical, optical, and philosophical skill. By conceding that such productions should be distinguished from art photography we by no means admit that we lower their dignity; the principles of their production bespeak the language of poetical beauty, inasmuch as they consist in the adaptation of the force existing in a ray of light to pourtray the object or scene from which it has been reflected. The twin sisters Science and Art undoubtedly coalesce together in nearer harmony in the productions of photographic results than in the kindred works of Painting, Engraving, or Sculpture.

Mr. Wall thoroughly endorsed the remarks made by Mr. Davis. He had urged such considerations in connection with the last exhibition of the London Photographic Society both in the British Journal of Photography and in the Photographic News, but the present question bore more especial reference to artistic photography, and he was glad to find this branch of the art had now created for itself a larger circle of enthusiastic friends than it once appeared likely ever to possess.

Mr. Davis thought it important that artistic photographs should be admitted as works of fine art; but also wished it to be remembered that illustrations of processes, such as those once exhibited by Mr. Burnett, which possessed the highest scientific interest, but were not in the usual sense works of fine art, should not be excluded.

The Chairman thought that some arrangement should be made for a proper classification of such subjects as Mr. Davis had referred to, together with photographs of machinery, anatomical preparations, &c.

Mr. G. Wharton Simpson said there could be no doubt whatever there were in photography, as in every other system of pictorial delineation, different classes of subjects, some of which possessed a purely scientific interest, others simply of a mechanical character, whilst others challenged attention as works of fine art. There could be no doubt also that, as photography embraced all these subjects, in a complete exhibition of the present state of the art, facilities should exist for the adequate representation of each. That part of the question might he conceived, however, be safely left in the hands of the Committee of Photographers, who should be appointed by the parent society, to co-operate with Her Majesty's Commissioners in case a satisfactory arrangement as to the classification were arrived at. Such a Committee would not be likely to fail in providing a fitting position for all illustrations of the scientific progress of photography, as well as of its capabilities in an artistic direction. The question now for their consideration was, whether they were to strengthen the hands of the parent society in its protest against the extraordinary classification into which, whether inadvertently or of intention, it was proposed to be placed by Her Majesty's Commissioners. He thought that as a society they were bound to give whatever force they could to the protest of the Parent Society, and aid them in securing, if possible, a classification more in accordance with the true character of the art. Personally, he could see many advantages in the separate department which the commissioners had stated they were willing to concede; he could see many practical advantages in such an arrangement. But the nominal insult would remain, and photography would be written down in the records of that great international undertaking as possessing no higher artistic claims than cart-wheels and ship's tackle. There was the sting. If the insulting classification could be removed, then he could see good reasons for accepting the arrangement proposed. In the meantime he thought it was their duty to express a cordial coincidence in the views already propounded by the Photographic Society of London in regard to this matter, and begged to propose for the adoption of the meeting a resolution to the effect. He had not intended to make any remark on the subject, and merely proposed his resolution in the absence of any other which might possibly better express the feelings of the meeting. The resolution was as follows:—

"That this meeting expresses its hearty concurrence in the steps already taken by the Photographic Society of London towards rescuing photography as an art from the degrading position in which it is placed in the proposed classification of Her Majesty's Commissioners for the International Exhibition of 1862; and desires to thank the Council of that Society for thus endeavouring to maintain the dignity of our art. That this Society desires further to express a hope that if it should eventually be deemed prudent, in lieu of any more satisfactory arrangement, to accept the separate department for apparatus and pictures offered by Her Majesty's Commissioners, that such department be accepted under a protest against any classification in the catalogue of the International Exhibition which does not recognise photography as one of the fine arts."

Mr. Wall had great pleasure in seconding the resolution, in the spirit of which he fully concurred.

Mr. Borchert suggested that the word "degrading" in the resolution was rather a strong expression. Perhaps the term "improper position" would as well express the meaning.

Mr. Simpson would not abate a jot of the full meaning of the word. If a stronger word could be found he would willingly adopt it; but nothing which would weaken its force. The position assigned to photography was really a most degrading one.

Mr. Davis remarked that whilst supporting Mr. Simpson's resolution, and feeling that art-photographs are works of art, at the same time would by no means undervalue the power of photography with respect to the importance of its non-artistic applications, or admit that its results are obtained by mechanical, instead of by chemical, optical, and scientific means. He added, that for the purpose of more perfectly recognising the distinctions he had pointed out he would suggest, with Mr. Simpson's permission, the addition of the word "art" to "photography" in the last clause of the resolution; so that it might be seen that it was for art-photography a position in the fine arts was claimed.

This addition was agreed to by Mr. Simpson and Mr. Wall, and the resolution was carried by acclamation.

Newcastle-upon-Tyne and North of England Photographic Society.

A special general meeting of this society was held in the Tower, New Bridge Street, on Friday evening, the 21st inst. Dr. Pyburn in the Chair.

The Secretary read a commuuication from Dr. Diamond, Secretary of the London Society, inviting their attention to that portion of the Regulations of the Commissioners of the International Exhibition of 1862, which relates to photograph also the letter of the Right Hon. Sir F. Pollock, and subseque correspondeuce, together with the letter of Professor Playfa and requesting their opinion upon the course which, in the interest of the art, ought to be pursued. He also read the resolutions drawn up by the Council which were submitted to them for sanction, rejection, or amendment. (See last week's News.)

The Rev. Dr. Lockhart, in a long speech, said that photography could not logically and philosophically be classed as a fine art. He said it not only is not in its present state, but never can, nor ever will be a fine art. He, however, denounced the absurdity of placing photography, whether used as meaning the photographic art, or the results, (specimens) of the art in the same section as machinery. He blamed the Commissioners for not perceiviug its being really so like and so much akin to the fine arts as to be entitled to rank as next to them, and its specimen in closest proximity to theirs.

Dr. Zenner, the Chairman, G. C. Warren, Mr. Laws, and Mr. Dewar entered into a discussion on the Rev. Doctor's speech.

Ultimately, after being well sifted, the resolutious of the Council were adopted. A vote of thanks was given to the Chairman, and the meeting separated.

SECOND ANNUAL REPORT OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

In resigning the trust you placed in their hands the Committee must proffer their congratulations upon the continued advancement of the Society in public estimation, the steadily progressive increase in the number of members, the number and importance of the papers which have been introduced, and the practical, animated, and *harmonious* character of the discussions.

Nineteen papers have been read at our meetings, in which the scientific, artistic, mechanical, and manipulatory elements of photography have each received attention, as will be seen by the following list of their subjects:—

On the Adaptation of Portrait Lenses to Views, by	C. J. Hughes.
On an Improved Portable Camera ...	G. W. Simpson.
On the Photogenic Action of Colour	T. Clarke.
On Instantaneous and Composition Photography	S. Fry.
On Positive Pictures on Glass ...	A. Hervè.
On some Optical Principles Involved in the construction of Photographic Lenses	W. Ackland, V.P.

Hints on Keeping and Composition Printing	A. H. Wall, *hon. sec.*
Art Photgraphy: its Scope and Characteristics	C. J. Hughes.
On Photography in Connection with Astronomy, Meteorology, and Magnetism	T. Burr, F.R.A.S.
On the Practical Details of the Fothergill Process	F. Howard, *hon. treas.*
On Photography for Wood Engraving	J. Contencin.
On a Visit to the Photographic Department of the Greenwich Observatory	G. W. Simpson.
On Intensifying Processes as Adjuncts to Instantaneous Photography ...	V. Blanchard.
On the Stereotrope	T. Clarke.
On the Solar Camera	S. Smith.
On Sharpness	A. H. Wall.

And the first, second, and third reports of the Experimental Committee.

The Committee take credit to themselves and the Society for having recognised the importance of photography as a department of imitative art, to which the principles and rules of pictorial science are as applicable as to painting and its kindred branches. The best thanks of the Society are due to its very excellent and rev. president for regular and constant attendance at its meetings, and for the efficient character of his services as chairman during the session.

The Committee have to thank the authors of papers read at the meetings, for their able contributions, and the kind interest they have thus displayed in the Society's well-being and utility.

The thanks of the Society are also due to Messrs. Hughes, Meagher, Davis, Simpson, Leake, and others for the exhibition of apparatus, &c. To Messrs. Bayley, Fitch, Blanchard, Smith, Simpson, Joubert, Davies, Wall, and others for kindly contributing to the folio, and to Messrs. Simpson, and Davies for gifts to the Society's library.

In the Society's first annual report several suggestions were thrown out, some of which have been successfully adopted, while others yet remain dormant. Among these, the Sub-Commitee appointed for testing and reporting upon new or modifications of old processes and prosecuting experiments in furtherance of fresh discoveries has been very happily carried out. The out-door meetings then suggested have also been adopted with general satisfaction to the members.

The Committee cannot permit this opportunity to pass without recording their grateful thanks to the following gentlemen, viz., G. Wharton Simpson, Sebastain Davis, Jabez Hughes, Borchert, and M. Hannaford, for their punctual and regular attendance, and their generous and valuable labours as members of the above Sub-Committee.

In entering upon the new year your Committee would suggest that the Society enter upon a new condition of existence for the following reasons:—

When the subscriptions of members have been used for the expenses incurred by the Society, for the Journal, and for the presentation print, it is found that the trifling balance remaining is not sufficient for the incidental expenses of warming and lighting the rooms, correspondence, &c., and that any thought of devoting small sums to the prosecution of experiments, or to other steps in connection with the advancement of the art, and, consequently, of the Society, would have to be completely abandoned.

To meet the above difficulty two paths were open. In the one, the subscriptions could be raised to a guinea per year, or an entrance fee, such as is usual in similar associations, be established. In the other, the Journal might be abandoned, and one subscription of half-a-guinea be adopted; the society pledging itself either to spend more money on the presentation photographs, or to increase the number of such, so as to secure two or more per year for each member.

Thinking the latter the better plan, your Committee recommend its adoption.

Another consideration in connection with the supply of a Journal, was, that in undertaking such distribution to members, the Society rendered itself responsible for the subscriptions of such, although the Committee could not always rely upon the receipt of the same from *all* the members. For instance, in several cases, last year's subscription remain unpaid up to the present time; and in one case the Journal has been supplied to a member for the two past years of the Society's existence, whose subscriptions, after repeated applications, also remain unpaid.

Influenced by the above, and thinking it wrong that the Society should be in debt to its officers, your Committee was contemplating the discontinuence of the Journal, when an event occurred which helped them very summarily to a conclusion.

The Publisher and Editor of *The British Journal of Photography*, placing an interpretation upon the connection existing between it and the Society, never directly or indirectly accepted by your Committee, and claiming certain exclusive privileges tending to cripple the independence of the Society, and retard its influence in propagating and advancing the art; such claims were not admitted, and an engagement made for a term with the Publisher, was, in consequence, by him, abruptly broken, although the Committee, resolving that their engagement to the members should be more justly carried out, procured the Journals at an increased rate of charge, and forwarded them post free as usual.

In consequence of this misunderstanding the hitherto pleasant connection between this Society and the *British Journal* has ceased. We can no longer be regarded as associated in any way with the trade interests of any particular periodical, and each member may select for himself such journal as best pleases his own taste or judgment, while by supplying at least two presentation prints per year, and rendering the Society even more actively useful in new departments, we must endeavour to fully compensate our members for what might otherwise be regarded as a something lost. We trust, therefore, that the support the Society has hitherto received, and we may fairly say *deserved* also, will not be withheld, and that the conduct of the Committee in supporting the proper dignity of their position, will give satisfaction both to the members and the friends of the Society.

The Committee, moreover, recommend that, instead of one, three Vice-Presidents be appointed; and that in addition to Mr. W. Ackland,* our present vice-president, they have received permission from Mr. Sebastian Davis, and the Editor of the Photographic News, Mr. G. W. Simpson, to nominate them for election, a step which we are sure will be thoroughly appreciated by the members generally, and do honour to the Society.

The Committee recommend that the following gentlemen be elected to serve on the Committee of the next year.

Messrs. Hannaford, Fry, Borchert, Blanchard, Quentery, Hughes, and Leake.

And that the Secretary and Treasurer be re-elected.

Also, that the following gentlemen be elected as members of the experimental Sub-committee:—

M. Hannaford.	W. Ackland.
G. W. Simpson.	Saml. Fry.
J. C. Hughes.	F. Howard.
Sebastian Davis.	M. Borchert.

It is usual to wind up annual reports with a glance at the progress made by the art during the society's year. This need not, however, prove a very tedious task, inasmuch as the fact is that no very prominent discoveries, or other important features have marked the history of photography since our last annual meeting. The vexed question of government competion with photographers had its day and seems likely to give place to a scheme for organizing an association which, if successful, will compete with the professional photographer through the aid of amateurs, more

* Mr. Ackland sent in his resignation before the meeting.

effectually, perhaps, than even the Government grant enables the South Kensington Photographic Department to do. The leisure of wealth, and the skill of labourers independent of their hire, who are satisfied with any remuneration which will pay even for the bare material, being rather formidable antagonists to that other labourer whose work buys *daily bread as well as the bare materials.*

Some promising steps have been taken in the adaptation of artificial light to photographic purposes. A good many firm-placed steps have indicated progress in an artistic direction. Modifications of more or less value in existing processes have been brought forward. Photolithography and photozincography have moved towards perfection.

Panoramic photography now appears to have made a fresh start. It is to be regretted that too many of our best and most artistic photographers—forgetting that upon such expositions the public estimation of their art is founded—sent nothing to the Photographic Exhibition of London (which was not, in consequence, so fair an exponent of progress, especially artistic progress, as it might have been). The Architectural Photographic Exhibition was a very excellent one; and of this, we are happy to add, no such remark as the above could be made. A new process, which will enable us to dispense with a sensitizing bath, has been announced as an idea conceived by Captain Dixon, and worked out by a member of this Society, Mr. Fry. Several other gentlemen, however, have laid claim to the idea, Mr. Bellini having previously announced the same in the Photographic News.

In conclusion, the Committee feel it their duty to proffer some remarks in connection with the position photography will probably hold in the Great International Exhibition of 1862.

This grievance is too well known to be here repeated; but every Photographic Society in the kingdom ought certainly to combine in suggesting, discussing, and preparing for such steps as may most vigorously oppose and defeat the foolish, unjust, and mischievous intention announced by Her Majesty's Commissioners of classifying pictures produced by optical and chemical science and artistic talent under the head of—heaven save the mark—Machinery!!!

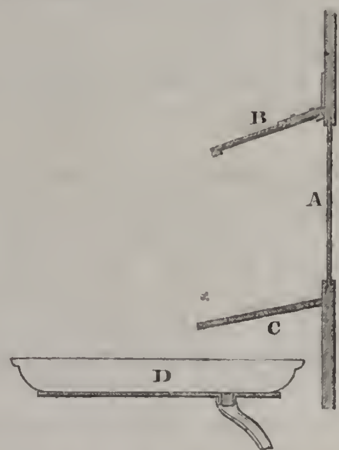
The following are the modified rules proposed for adoption:—

1. That this society be called the South London Photographic Society.
2. That this Society hold its meetings on the second Thursday of every month, to read papers upon photography in any of its various departments, and discuss the same; to prosecute experiments, exhibit apparatus and specimens, &c.
3. That nine in-door meetings be held from October to June inclusive, and that out-door meetings, as may be appointed by the Committee, be held during the three intervening months.
4. That the number of members be unlimited; and that all candidates for admission be nominated by one member, seconded by another, and elected by show of hands.
5. That ladies be eligible to become members.
6. That every member be privileged to introduce a friend at the monthly meetings.
7. That the subscription be half-a-guinea per annum, *payable in advance*, and a payment of five guineas in one sum, constitute a life member.
8. That the Committee be empowered to arrange soirées, conversaziones, exhibitions of photographs, appoint Sub-committees for conducting any particular series of experiments &c., as the Society's funds may permit.
9. That no member be deprived of his privilege unless by a vote of three-fourths of a special meeting.
10. That the annual subscription be due upon the second Thursday in June, at which meeting officers are to be elected for the ensuing year.
11. That the management of the Society be conducted by a President, three Vice-Presidents, Secretary, Treasurer, and a Committee of eight; four to form a quorum.
12. That a full report of the Society's affairs be laid before the members at the annual meeting.
13. That the Secretary have the power of convening a special meeting on receipt of a requisition signed by half-a-dozen members.
14. That no alteration be made in these rules except at the annual meeting in June, or a special meeting convened for such purpose.

Apparatus.

AID TO DEVELOPMENT.

Sir,—I have lately made an addition to my dark-room window which enables me to develop the negatives and positives with much greater certainty and ease than before; and as it is easily applied to almost any dark-room some of our readers may like to try it also.



A is the yellow-glass window of the dark-room, 11 × 9 inches; B a peice of looking-glass, 11×6 inches, fitted into a slight wood frame and hinged to the wall of the dark-room; C is a piece of slate painted white, 11×6; D developing tray. The glare of light coming in at the window is thus shielded from the eyes and from the plate; and being reflected on to the white slate it is much easier to see when the negative is developed to its proper depth.

For clearing silver baths I have found common washed whiting to answer better than kaolin, citric acid, or chloride of sodium.—Yours truly, Thos. Gulliver.

17, *Heathfield-street, Swansea.*

WOODEN BATHS FOR THE SILVER SOLUTION.

The use of wooden trays for the various solutions used in printing has often been advocated, and operations on such an extensive scale as that rendered necessary by the solar camera, render them little less than a necessity; but the use for wood to hold a nitrate bath for collodion plates has not been tried to any great extent. According, however, to some of the writers in the *American Journal of Photography*, they are likely to come into general use amongst our cousins in the States. Mr. E. K. Hough, writing on the subject, remarks:—

"The veriest tyro in chemistry must know that the most essential qualities of the bath should be its perfect neutrality to the nitrate solution, neither affecting it nor being affected by it. And among all the materials used, including gutta percha, rubber, earthenware, glass, porcelain, &c., I believe there are none that excel a well-made wood-bath, lined with shellac, in the combined qualities of strength, durability, shape, and lightness and convenience of handling for the purposes intended, and last, but not least, the low price for which it can be constructed.

"I know of several operators who are using wooden baths, and I am now using one that takes a plate 14 × 17ins., made of common well-seasoned inch pine plank, with strips on sides and bottom 1½-in. square, closely set with tongue and groove, and all strongly held by large screws 2 inches apart, leaving the chamber for the solution 16 × 21½ins.; this bath was coated with shellac six months ago, and has been in active daily use since, without the slightest apparent depreciation of either the solution or the vessel itself. In that there have been added several pounds of silver and gallons of water without any tendency to fogging or any other morbid action, nor has it been necessary to add a single drop of either acid or alkali, and the solution now remains as clear as water, which is more than I could say of many other baths I have used except glass. One end of the bath is hollowed under, like the nose of a pitcher, and the contents can be turned from it as readily, without losing a drop.

"This bath only cost the modest sum of four dollars, which was high at that, while most of the good baths in the market of that size would cost from twelve dollars to twenty-five dollars. Such a bath can be constructed at very short notice in the most retired village, and might be remembered to advantage by those country operators, whose present bath should surreptitiously give way, from accident or old age, without due notice, thus leaving them sadly in the lurch.

"And I would recommend all operators who think of getting new and larger baths, to visit the most careful and ingenious carpenter in their vicinity, and engage him to construct a vessel for two or three dollars, and turn into it a quart or so of shellac, a little more fluid than mollasses, and when it is well coated all over, to turn off the surplus, and leave it until thoroughly dry. Then he may turn in his best negative or positive bath solution without the slightest fear of evil consequences; occasional drying and shellacing is of course advisable, but unless it leaks is rarely necessary."

Mr. P. C. Duchochois, writing on the same subject, remarks:

"As wood for silver baths is likely to come into general use we should determine the best method of constructing them. I offer a few hints on the subject, partly from actual experience, and partly from consideration of the nature of the materials with which we work.

"The wood should be thoroughly seasoned, in order that the pores may be open to receive the shellac; the gum must be allowed to penetrate the substance of the wood far enough to take hold of the fibres. In order to have the wood free from injurious matters contained in the sap, it might be worth while to give it a good soaking in running water, finally drying it by artificial heat if necessary.

"The matching of the joints should be truly made, and thick varnish be used instead of glue. When iron screws are used they should be so placed that the solution cannot in any way reach them; the heads should be sunk in and well varnished.

"After the bath is put together, it should be filled with thin shellac varnish, and kept so for a day or two. The varnish being thin will penetrate the wood and saturate it thoroughly. When the thin varnish is poured out it may be replaced by a varnish thick enough to give a suitable glazing. If very thick varnish be used at first there is danger that it will crack and scale off on becoming dry.

"Pans for silvering paper or salting, may also be made of wood, which will be found as serviceable and far cheaper than of materials commonly used."

The method adopted by Mr. Francis, of working in a thin sheet of pure india-rubber as a lining to a wooden bath, must, we apprehend, be simpler in application, and more satisfactory in result than a mere varnish of shellac, which must be constantly liable to chip and abrade from contact with the edges of the glass and the bottom of the dipper. We intend shortly to try one of the india-rubber lined baths, and report upon it.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 26th June, 1861.

The competition for the Duc de Luynes' prize of 2000 francs for the perfecting of the positive printing of photographic proofs, either by old process, or by new carbon processes, will close on the 30th instant. The decision as to the other prize of 8000 francs for converting positive pictures into plates which will serve to yield a large number of proofs by the processes by which engravings or lithographs are produced, without the intervention of the human hand in the design, has been postponed until the 1st of July, 1864.

Photographers will perhaps need to be reminded that the Exhibition of the Industrial Arts, to be opened at Brussels on the 1st of August next, will include a section specially appropriated to photography. Pictures intended for exhibition must be sent previous to the 5th of July next, and notice of the same previously to M. Dulieu, Secretary of the Association of Industrial Arts, Palais Ducal, Rue Ducale, Bruxelles.

Another Photographic Exhibition will open in September next, at Marseilles, under the direction of the Photographic Society of that city, the secretary is M. Lion Vidal, Rue Mazagran, 2, a Marseille. Pictures now in the Paris Exhibition can be forwarded direct to the Marseilles Exhibition, by addressing the secretary of the Paris Exhibition to that effect.

M. l'Abbé Laborde has addressed to our photographic Society the following communication upon the action of iodine in the silver bath.

Generally, we endeavour to give the greatest possible sensitiveness to collodion film, and one of the most efficacious means of so doing consists in employing a silver bath saturated with iodide, and quite neutral. But this neutrality exposes us to another evil, which we inevitably fall into, if, at the same time, we direct all the other operations towards extreme sensibility; a general veil or *fog* covers the proof, and shows itself principally on the *reserves*. The *reserves* are those parts of the proof upon which the light has not acted; this term will be found very convenient, for it designates without confusion similar effects by the same word, the *whites* of the negative proof and the blacks in the positive upon glass. We must, therefore, resign ourselves to the loss of some sensibility, either by modifying the whole of the processes, or in giving to the silver bath a slight acid reaction.

M. Laborde has found a new method easily put in practice, and which, in preserving the same degree of sensitiveness in the collodion film, gives also great purity to the reserves. This method consists in introducing some iodine into the silver bath saturated with iodide of silver; about 1 part to 200 parts of liquid. The bath is shaken from time to time; and after a contact of four-and-twenty hours, a silver bath which has caused the negative to fog will have become regenerated, so to speak. We cannot apply the ordinary laws of chemistry to this fact; or, rather, we must search deeper into these laws to find an explanation of it. For every chemist will think that iodine in contact with nitrate of silver will remove the silver, and set some nitric acid free; this acid would then act like most other acids, in opposing the reduction of the silver upon the reserves. But it is found that the prolonged contact of iodine with the silver bath, well saturated with iodide of silver, does not cause it to lose its neutrality; the nitrate bath containing iodine may be heated nearly to ebullition without manifesting subsequently any acidity. We can employ this means if we wish to obtain in a few minutes the whole effect of the iodine upon the silver bath.

However, when the iodine has remained fifteen to twenty days in the bath, a yellowish tint may be observed on its surface: the liquid then possesses, sometimes, a slight acid reaction; but this tint has a secondary action, which must be attributed to air dissolved in the silver bath. The yellow tint manifests itself by lineaments which correspond to the grains of iodine where the imprisoned air has been drawn into the liquid; and if we see a bubble of air fixed on the surface of the iodide, we may observe subsequently that it has disappeared. and become replaced by a yellow spot. In making the experiment in a flat plate, inclined so as to put the iodine in contact with the air and the liquid, some iodide of silver will be formed around the fragments of iodine, and the bath will lose its neutrality. From this we may understand that the iodine must be entirely immersed in the liquid, and that it is best to withdraw it when it has produced the desired effect. It is easy to restore the neutral state of the bath by adding some carbonate of silver. We can even leave an excess of carbonate of silver in the silver solution, without its losing any of the properties it owes to the presence of iodine; this fact proves still more that they are not due to nitric acid, else we should have to admit the existence in the body of the same liquid of the prolonged existence of two substances which mutually attack each other. Besides we know that the feeblest proportion of nitric acid diminishes much of the sensibility; and if the dose be a little strong, the proof becomes flat, because it refuses to strengthen under the developing agent. When the nitrate of silver is not saturated with iodine, matters proceed differently: the iodine removes some silver from the nitrate, and sets some nitric acid free: the iodide of silver dissolves in the silver solution, which soon becomes very acid. We can neutralize it by carbonate of silver, but it is much better to dissolve the iodide of silver in the nitrate, and add the iodine only after complete saturation.

The effect of iodine in the silver bath consists, probably, in preventing that spontaneous reduction upon the sensitive film which often takes place without the luminous action. The silver reduced in advance called afterwards the reduction of the nitrate under the developing agent, without any well marked preference for the impressed parts when the first reduction has been rather strong, a general *fogging* results, which really does not cover the image, as it pre-exists, and is formed as promptly as the image. We see by this how important it is to prevent this veil or fog.

In this modification of the bath, it is remarked that the proofs solarize with difficulty; to do so, they would require much longer exposure than ordinary. Solarization is doubtless very often attributed to the subjacent veil spoken of above, then we diminish the time of exposure; thus by pursuing a false route from which we can only emerge with mediocre proofs in our hands.

Photographers have long known that we must almost always attribute to the silver bath the imperfections which torment them so keenly by the obstinacy with which they reappear; in iodine will be found a powerful auxiliary for avoiding most of them.

DEPTH OF FOCUS.

"Who shall decide when doctors disagree?"

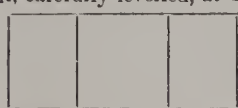
SIR,—It is a fact which seems often forgotten by the "scientific" gentlemen who occupy most of the time at the meetings of the Photographic Society that the extremely animated discussions with which they favour us will not alone suffice to illustrate the powers of photography. "Palabras! Palabras!" as the Spaniard says, whence Palaver—mere words, whether fair or otherwise—butter no parsnips. I often think it would be much more to the purpose if they did more and talked less. The practical result—without which the art would remain an optical and chemical theorem—is—a picture, and it appears to me that the "scientific" ideas respecting "depth of focus" recently advanced tend considerably to puzzle those who, wanting to produce the picture aforesaid, trust at the same time to their oracular dictates.

I maintain that there is such a quality as "depth of focus," and that it is of the most essential necessity to the production of the photographic picture.

"Focus" I take to be the point of most perfect definition in the delineation by the photographic lens of a subject or object; but this mere point or line to which we are to be tied down is, under certain conditions, capable of extension, relatively or absolutely, in the subject, and then I consider the term "depth of focus" correct.

To illustrate my assertion:—at the full aperture of a 6-inch double lens of long—say 24 inch—focus, the point *a* being focussed, the shallow line of correct definition traversing the object or subject is in immediate contact with buzzy indistinctness, which may be theoretically scientific, but which, in practice, is artistically hideous. If we now diminish area of aperture by a stop to 5-in. diameter, we find that not only *a* is well defined and "in focus," but
— *e* that *b b* leaves the buzzy haze and appears also defined.
— *d* Putting in 4-in. stop, *c c* are as good as *b b*, with the
— *c* former; 3-in. aperture will relieve *d d* from its ob-
— *b* scurity; whilst 2-in. will give a condition of *printed*
— *a* *picture* in which the mathematical LINE, which was
— *b* the appearance presented, has been deepened and
— *c* extended in such a manner that for all practical
— *d* purposes it includes with equal goodness of definition
— *e* to *c c*, whilst the drawing of the most extreme points
is relatively ameliorated.

Or otherwise, taking six lenses of the respective focal lengths of 18, 15, 12, 10, 6, 1½, and, focussing each upon *a*, we observe that 18 inches only gives a *line* correctly, but that 1½ includes the two extremes, and that pro rata of diminution of focal length in our lens, we have more and more depth of focus in our subject. Now it appears to me that if there is no perceptible difference in the definition, or "sharpness" in the picture, of two objects situated in different planes in nature that the term "Depth of Focus" is a very legitimate and proper one to express the quality described. Nor, in my experience, is it at all a necessity that possessing such a quality should be indicative of faulty correction, for spherical or chromatic aberration in the lens. Ecce signum; I have a 4½ double lens by the late Andrew Ross, 13 inches focus to parallel rays; at *full aperture* I point it, carefully levelled, at 18 feet distance on the window of



my dining-room, and on a 12 + 10 plate the result allows a straight edge to prove the perfect and exact square and *truth of the lines*. I have many quasi and *absolutely* instantaneous pictures, some of the latter 12 + 10 in size, showing its *rapidity*, whilst the certainty of its best definition, being precisely that sought for, shows in the result that the chromatic aberrations have been perfectly corrected. Practically, I cannot call such a lens other than very perfect for the multiplicity of uses to which I have had occasion to put it.

Considering one iota of tangible result worth any amount of "Palaver," I send you, in proof that there is such a quality as "Depth of Focus" in a *good* (the before-mentioned) lens. A trial plate taken just before a recent public ceremonial; you perceive 10 + 8 size of picture, 3 inches aperture, on 4½; time, 4½ p.m. on a rainy, dull day, as the umbrellas show; exposure, *two seconds*. Referring to the printed placards, which happen really to form quite "a test for a lens"—you perceive that the definition is absolutely equal in those in the foreground, and in those behind, although not less than 100 feet of distance intervene.

Surely, sir, this is "Depth of Focus," if not, I should like to have a scientific denomination, which would better describe the quality.—I remain, your obedient servant,

LAKE PRICE.

[The proof forwarded unquestionably confirms the position assumed by Mr. Price. The letters on placards in the foreground and furthest distance, including a range of 100 feet are perfectly legible. The print illustrates what we meant in our last week's article by the term "sufficient definition," although it is possible that cavillers on the opposite side might say there was no perfect or microscopic focus at all. Those who know the late Andrew Ross's lenses will understand, however, how to regard such an objection.—ED.]

Talk in the Studio.

Photography by Machinery.—A very elaborate specification has been published detailing the particulars of a process for the rapid re-duplication of photographic proofs by the aid of machinery, the invention of Mr. C. Fontayne Flounders of Liverpool. The sensitive paper revolves on a roller under a negative, tho light upon which is concentrated by means of a condenser. Tho method of printing by development is adopted in connection with this invention.

Exhibition Medal.—Mr. D. Macliso has received instructions from tho Royal Commissioners for the International Exhibition of 1862, to prepare a design for prize medal.

Photozincography.—A fac-simile of a portion of the Domosday Book MS., relating to Cornwall, has been just completed by Col. James at Southampton, and is ready for issue to the public.

"Light" in the Sea.—Dr. Wallich, in a recent paper on Nature of tho Deep Sea Bed, read at the Royal Institution, says: "Light, or rather the absence of it, can hardly bo said to determine, in any important degree, tho distribution and limitation of the lower forms of animal life. Light is not essential even in the case of some of the higher orders. A largo class of creatures, both terrestrial and marine, possess no truo organs of vision, although there is good reason for believing that they do possess somo special sensory apparatus, susceptible to the influence of light; whilst certain creatures, whose habitation is in subterranean caves or lakes, as in tho Magdalena caves, near Adelsburg, and tho Great Mammoth cavos in Kentucky, either possess no organs of vision, or possess them in so rudimentary a state, as to prove clearly that the absence or imperfect development of this sense may bo compensated for by the higher development of other senses. It is quito impossible at present to say to what depth light penetrates in tho sea. Tho photographic art will, no doubt, one day solve the problem. But it is almost certain that a limit is attained, and that, moreover, long before the deep recesses guaged by tho sounding machine are reached, where the light-giving portion of the ray cannot penetrate even in tho most attenuated condition; and yet, as shall hereafter be shown, creatures have been found down in those profound and dark abysses whoso colouring is as delicato and varied as if they had passed their existence under the bright influence of a summer sun!"

The Camera v. the Rifle.—The *American Journal of Photography* states, that at the recent meeting of the American Photographic Society, a corporal's guard of members only turned out, and after transacting tho routine business, dissolved at once, that they might form themselves into squads to discuss the state of the war.

To Correspondents.

M. M. D.—There is very great risk of injuring an unvarnished negative in printing transparencies by superposition of a wet plate, however carefully the plate may be drained. For such a process the negative should be well varnished. If you do not wish to varnish the negative by camera printing.

A. F.—Very few quarter-plate lenses will produce standing portraits of the carte de visite size with anything like success. Sitting figures are more easily managed, as the position of the figure is more easily adapted to the curved field of the lens. If you have length of room enough, use a half-plate lens, if not, procure one made expressly for the purpose in question. 2. See an article in our last number, on this subject, by Mr. Eliot.

S. G. E.—We cannot tell you with any definiteness the prices charged for enlarging with the solar camera. They vary abbording to circumstances. We believe, from about half-a-guinea to a guinea.

Thos. Smith.—Whey is made by adding rennet, which is the preserved stomach of the calf, to skimmed milk. It may also be made by adding acid to milk. Perhaps the best method of preparing it for photographic purposes, where it cannot be procured ready, or where the rennet is not at hand, is by means of lemon juice, about two tablespoonfuls to a quart of skimmed milk. This should be boiled, and the curd removed by straining through linen. This is the method to which you refer as recommended hy Mr. Sutton. An article on the benzole waxed paper process recently appeared in our columns. A resumé of the Rev. J. Lawson Sisson's "Turpentine Waxed Paper Process," as given in the pamphlet published by Marion and Co., appeared in our second volume, p. 277. We havo seen some most exquisite results produced by it.

G. G.—In French polishing the finishing polish with a little spirit alone may be dispensed with if you choose. Its object in the hands of those who are skilled in the manipulations is to give a higher and more perfect polish than had been attained in the earlier operations. It requires the application of very little spirit, and a light and skilful hand. The subject of republishing the "Amateur Mechanic" has not been forgotten. It will have additional chapters on polishing &c., when it appears.

Very Troublesome.—Your negative is not nearly sufficiently dense. Get a much denser negative, and print much deeper. You cannot print deeply without a negative dense enough, and without sufficiently deep printing you cannot effect much in the way of toning. Your negative is not sharp; always focus for the eyes.

F. J. G.—Two or three grains of gallic acid to the ounce of water will do for the final application to Fothergill plates. We continue to hear very good accounts of the results. Letters intended for answering in the same week's News should never reach us later than Thursday morning, as we go to press on the evening of that day. Yours reached us on Friday, after last week's paper was printed.

Perseverance.—The terms "negative" and "positive" as applied to different qualities of paper had their origin when the calotype process was more in vogue. The negative paper was the thin fine paper suitable for producing paper negatives, printing more rapidly, and showing less of the texture of the paper than the thick papers. The terms are still sometimes used as descriptive of the papers, even when intended simply for positive prints. What is termed negative paper is generally preferred for stereoscopic prints. 2. We see no reason why the pair of lenses you have should not answer for stereoscopic views if the focus and action of each is the same. Being portrait lenses you must use a central stop to make them available for views. If you use a plate seven inches long you can place the lenses any distance from 2½ in to 3½ in. apart. It is sometimes convenient to have a lateral movement so as to be able to vary the distance slightly.

Tannin.—Either 2 or 3 are good; perhaps a mixture of the two will prove best.

R. C. R. B. J., India.—The iodizing solution you use is very good, but you would probably find an advantage, in an Indian climate, in the entire use of iodide of cadmium or the substitution of iodide of sodium for iodide of potassium. You will be able to obtain the alabastrine solution of Messrs. Le Page and Co. You will have already seen that we have published all that is known of the process of Mr. Bellini. The albumen process is only used for landscape purposes or transparencies. Collodion is better for portraits, although we have heard, as you state, that Signor Beato took portraits on albumen in India. We prefer a twin lens camera for stereoscopic pictures, whether portraits or views. Calico, painted dark grey, is the best for a background. The redness and thinness in your negatives, when over-exposed, is due to what is termed solarization. The best remedy is the addition of citric acid to the developer; about half a grain to each ounce of solution. Your collodion losing its colour, after first being dark is not necessarily a defect. We see no reason to believe your silver bath in fault. The formula of Powell's collodion is known only to the makers. Many of your questions have been recently answered, and articles on the subjects you inquire about have been recently published in our pages. We recommend you to procure Hardwich's "Manual of Photographic Chemistry."

C. F. E.—Negatives, intensified by means of bichloride of mercury must be varnished. It is not absolutely necessary to varnish negatives produced in the usual manner, except for their protection. Varnishing sometimes slightly reduces the intensity.

Tit Tat To.—The collodion is most probably in fault. Try another sample, or add a little of an older collodion to it. The gallic acid solution would probably answer your purpose. A two or three grain solution may be used, and is poured over after all the other operations are completed, and left to dry without further washing. The chloride of ammonium in the albumen solution gives greater certainty of freedom from stains, but sometimes diminishes the intensity a little. Negatives from dry plates, if they are full of detail, as you describe, but are wanting in force, may be intensified with bichloride of mercury, the same as negatives by the wet process.

J. T. Barber.—The process will be published shortly.

F. G. Jackson.—Your nitrate bath has far too much free nitric acid for negatives, one drop to the ounce is a full dose, even for a positive bath. Add a little oxide of silver, which will be converted into nitrate of silver, and thus remove the free acid and strengthen the bath at the same time.

John Picken.—Pure whites and deep blacks in glass positives depend upon all parts of the process being in proper relation, rather than on the developer only; but the addition of nitric acid to the developer, about one drop to the ounce, generally improves the whites. To begin at the beginning: use a strong nitrate bath not less than 35 grains or 40 grains to the ounce, and a drop of nitric acid for each ounce of solution. Use a strong-bodied collodion made from pyroxyline at a low temperature. Develope with a mixture of protonitrate and protosulphate of iron, made as follows: dissolve 1 ounce of powdered nitrate of baryta in 16 ounces of water, add 2 drachms of nitric acid. Then add 1½ oz. photosulphate of iron, and shake the whole till it is dissolved. Then filter carefully to get rid of the white insoluble sulphate of baryta which is formed. The solution loses its strength if kept long; this may, in some degree, be remedied by adding from time to time, as it gets weak, a little more protosulphate of iron. Add sufficient alcohol to make it flow freely. A few drops of tincture of iodine in the collodion help to keep the blacks clean. Carry out these hints, and you will get rich positives with pure whites and deep blacks.

R. Elgie.—The stains are not caused by the mounting. They appear to consist of the insoluble hyposulphite of silver, and most probably occur from nitrate of silver coming in contact whilst hyposulphite of soda remained in the print, or from hypo coming in contact whilst silver was in the print. The insoluble hyposulphite of silver once formed in this way is never removed, it does not show much at first, but gradually darkens to a dirty greenish brown.

J. A.—The streak in your print arises from the paper. It is difficult to say whether it is from some fault in the original paper, or imperfect albumenising.

N. H. W.—We do not quite understand your description of your intended glass room. After stating the dimensions, you say "there will be two feet of woodwork at the end where the sitter will be, and twelve feet from that in length at the sides and top." Twelve feet of what? Send us a rough diagram in your next, and we shall have pleasure in giving you our aid in the matter. Try the addition of a few drops of tincture of iodine to your collodion, or a little more acid in your bath.

*** Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 148.—*July* 5, 1861.

M. ROMAN'S MODIFIED TAUPENOT PROCESS.

It will be interesting to those of our readers who already practise the collodio-albumen process, and are anxious to produce the rapid results referred to in M. Chevalier's pamphlet, to know that they may do so with their plates prepared in the ordinary manner; the only modification in the usual practice being the use of a hot developing solution.

One of our correspondents, a gentleman who has had very large experience in the dry processes, informs us that he has recently made some experiments on M. Roman's process, full details of the results of which we hope shortly to receive. He has already arrived at conclusions which justify him in believing that in the use of the hot developer the true source of the rapidity exists. A plate prepared by the collodio-albumen process, as he usually practises it, was exposed for three seconds with a Ross's stereo single lens, and then developed with a hot solution of pyrogallic acid, and was found sufficiently done. For the satisfaction of those who may wish to repeat the experiment, we may briefly state the method adopted by our correspondent in the preparation of his plates. A bromo-iodized collodion is used, and after exciting, the plate is first washed in a dish of distilled water, and then thoroughly in common water. It is then coated with albumen containing chloride, iodide, and bromide of ammonium. The final exciting bath contains thirty-five grains of nitrate of silver, and thirty minims of glacial acetic acid to an ounce of water. After exciting, it is well washed; and after getting rid of all free nitrate, is coated with a two-grain solution of gallic acid, as originally suggested by Major Russell; the plate is then dried.

We hope in the course of a week or two to publish the results obtained by our correspondent more at length. In the meantime we shall be glad to learn if any other of our correspondents have been experimenting in the same direction, and with what success.

PHOTOGRAPHIC EXHIBITION AT MANCHESTER.

The Manchester Society is resolved to take time by the forelock, and has, some weeks ago, issued a prospectus—which, by the way, from some singular oversight of the secretary, we presume, never reached this journal—of an exhibition intended to be held in connection with the British Association for the advancement of science, the meetings of which have to be held in Manchester in September next.

The committee formed for the purpose of carrying out the arrangements propose to organize the exhibition upon a plan which they believe has not hitherto been attempted, and solicit the aid of all interested or accomplished in the art, to assist them.

"Photography," they observe, "is no longer an art which merely gives us interesting pictures in landscape and portraiture; nor is it a fixed thing, conducted upon one set of established rules, for we now find it applied to a large number of objects and uses, and conducted upon many methods differing materially from each other. It is particularly the aim of the present undertaking to show its capabilities in these respects. At a gathering like that of the members of the British Association, men of all shades of taste and acquirements in scientific pursuits are brought together, and it is thought that by making the proposed exhibition the means of showing how photography may be applied to their several pursuits and requirements, that a great end will have been attained; not only by affording amusement for the time, but by gaining a more extended patronage of the art, and securing the co-operation of many who are at present totally unacquainted with the wide field of subjects to which it may be made subservient."

The objects of the committee are decidedly laudable and worthy of the aid of photographers generally. We would suggest, however, to the committee that they scarcely best serve the purpose for which they are appointed, by neglecting, either of intention or otherwise, to avail themselves of every means of publicity open to them.

It is proposed to classify the specimens exhibited, somewhat after the following method :—

I. Present state of the Art, as illustrated by views, portraits of eminent persons, &c.

II. The Practical Application of Photography to copying machinery, maps, paintings, statuary, rare engravings, geological strata, &c.

III. The various applications to engraving, lithography, wood cutting, &c.

IV. The History of the Art, as shown by some of the early efforts of Daguerre, Talbot, Archer, and others, with specimens of the various processes, such as Daguerreotype, calotype, wax paper, collodio-albumen, &c.

V. Various experimental processes, such as prints with uranium, platinum, carbon, &c., and numerous curiosities in Photography.

VI. Photographs with the microscope and telescope.

VII. The most recent improvements in Apparatus.

It is submitted, that not only photographers, but those also who merely take an interest in the Art, may assist the Committee materially in more than one direction. Those who do not themselves work at photography may possess and be willing to lend the productions of others, or to canvass their friends for choice or peculiar specimens of the Art, and all may assist by encouraging an interest in the Exhibition, and by affording hints or counsel as to the practical carrying out of the design.

A detailed scheme of the rules to be observed by exhibitors will be issued in due time.

ART PHOTOGRAPHS.

We have received from Messrs. Jackson Brothers, of Jumbo, near Manchester, specimens of a series of photographs in the Medlark Valley.

Than these we have seen few photographs more pleasing to the artistic eye. The subjects are of the more familiar and common-place kind: the homely features of a country lane, and such scraps of village life as one might gather in plentiful abundance, during a summer afternoon's ramble on many a country road, constituting the elements out of which, by attention to the rules of art, and careful photography, these very excellent pictures have been created. Such subjects as the Dutch masters of painting delighted in seeking are here shown to be as valuable to the photographer as to the painter, while the careful imitation of texture and detail is as characteristic of photography as of Dutch painting.

Nearly all these landscapes have figures introduced, and, with one exception, these are exactly in the right places, doing just their proper work as elements of composition, and strengthening the sentiment or feeling of the whole. Let us glance over this charming little collection.

The Milk-boy's Return.—In a narrow rustic lane, dappled with sun and shade, we see a milk boy jogging leisurely towards home with his milk-cans and donkey; a child has paused to rest by the way; and a distant figure is approaching in the same direction. They are all coming one way, doubtless towards some town or village; at any rate this is the suggestion, and such a suggestion is of no small value to the picture, which is a most charming one.

Red Bill's: Daisy Nook.—In the picturesque porch of an otherwise modern cottage, sits a contented-looking fellow, placidly enjoying a pipe, while two other figures, a male and female, rest upon the low and dilapidated wall in an attitude suggestive of a cosy chat. A third figure in the background leans over a gate. It is evident that work is over for the time being, and that rest is a very enjoyable luxury. Grouping, posing, lighting and tone all suggest repose.

Watt's First Engine.—A boy bearing his satchel from school comes up and stands in an attitude expressive of earnest thought before the picturesque ivy-grown old relic of "Watt's first engine." The straight line of a very unpicturesque hill cuts the picture near the top, and a straight row of angular brick and tile cottages, each with two windows and one door, and every window and every door exactly like each other, is on the right. But, nevertheless, this, like the rest, is *a picture*, pleasing at a glance those who know nothing about composition, and pleasing yet more, after a long look, those who know all about that sort of thing.

Ancient Cottage, A.D. 1410.—The gable end of a very picturesque ancient cottage. Milk-cans on the right, other domestic utensils on the left; a yard paved with what have been termed "petrified kidney potatoes," and overshadowed with trees; a group of three figures, as essentially belonging to the milk-cans and kitchen utensils, as the latter do to the cottage; and there, too, is a picture, which brings a smile to the lips of the most common-place observer, as they part, in uttering, "Bless me, how natural!"

The Ware: Daisy Walk.—A foreground, formed by a picturesque female figure about to wade into the water; other figures leaning listlessly over a rude rail, and watching a narrow stream tripping over rugged, irregular steps of stones, after emerging from a dark arch; yet other figures, engaged in conversation, a fine group of trees, some distant cottages, and again other trees beyond. These constitute the picture, and it would astonish the uninstructed observer could the figures be removed to see how much of the picture's real interest belongs to them. One figure, bye-the-bye, is badly placed. It is that of a seated boy, backed by a dark shadow, the boy's face is the lightest, the shadow is the darkest part of the picture, and the two thus brought into immediate contrast form a focus just where such a focus has no right to exist. This is the one exception above-named, for the boy occupies just the position on the one side that a man's figure fills on that exactly opposite. The oval shape, the breadth, unity, and clearness of the whole is charming. As to that obtrusive boy, we no sooner saw his patch of a white face than out it went behind a dab of crayon which lay at hand, and we sighed a sigh of great relief to find it "gone from our gaze."

Medlark Valley Farm is a farm-house, and a quiet valley leading thereto, with a couple of rustic figures sauntering along it. These figures, although not badly placed or obtrusive, are the only ones in the whole series which show that they have been placed, and look conscious of "being taken."

We have thus pointed out the subjects of which these very artistic photographs were created—subjects within every one's reach—in order to impress upon our readers the importance of pictorial rules as elements of the picturesque. When they first reached us we were at home, and in the company of friends; professional artists, professional photographers, and those who were neither. By all were they admired, and by all they were said to be peculiarly beautiful. Now, as there is nothing peculiar or uncommon in the subjects themselves, we have every right to attribute to artistic treatment the many charms these photographs undoubtedly possess.

One peculiarity remains to be noticed, viz.: that while the figures are as important as the landscape, they are not more so; and that while the landscape has beauties of its own, they do not detract from, but harmonize with, those belonging to the figures. A few such pictures as these of Messrs. Jackson, Brothers, will soon convince folk that photography has no mean power as a fine art, and that it is mere folly to kick against the steadily advancing tide of its progress.

The photography, apart from the art qualities, is throughout good. There is no under-exposure; no opaque masses of black, no glaring chalky patches of white; but plenty of detail, softness, and vigour; whilst the tone is warm and pleasant and adds much to the sentiment of the pictures by harmonizing with it. We should like to suggest to the artists the value of a little more margin in mounting; but it is possible that the exigencies of the post demanded that those sent to us should be a little curtailed.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Cyanide of Potassium (*continued*).—Having given the best methods of preparing cyanide of potassium, we next pass on to the properties of this salt. The pure salt, obtained by crystallization from an aqueous or alcoholic solution, forms anhydrous octohedral crystals, which, at a dull red heat, decripitate slightly, and fuse to a transparent and colourless liquid; at a higher temperature, approaching a white heat, the salt volatilises unchanged. When quite dry it is inodorous, the smell usually accompanying the commercial article arising from the carbonic acid and moisture of the air decomposing it with liberation of hydrocyanic acid. It has a strongly alkaline and bitter taste, resembling hydrocyanic acid. It is alkaline to test paper, and is very poisonous. The poisonous properties of this salt, as well as the most appropriate means of counteracting its deadly effects, have been recently so fully discussed in our "Scientific Gossip" column, when commenting on the late fatal case of poisoning by its means, that further allusion to this is rendered unnecessary.

Cyanide of potassium dissolves very readily in water. Its aqueous solution may be kept unaltered in close vessels at ordinary temperatures, but when boiled it is decomposed, forming ammoniacal gas and formiate of potash. This decomposition is, however, not complete unless the boiling be continued for a considerable time. If the solution is boiled down with free access of air, a larger quantity of carbonate of potash is formed than of formiate of potash, and hydrocyanic acid is evolved in abundance. When moist lumps of cyanide or its aqueous solution are allowed to remain in contact with the air at ordinary temperatures, it gradually absorbs carbonic acid, evolving hydrocyanic acid, and becoming converted into carbonate of potash. The dry lumps when exposed to the air deliquesce and become wet, when the same decompositions take place.

In absolute alcohol cyanide of potassium is almost insoluble, one part requiring 80 parts of boiling spirit of 95 per cent. to dissolve it. It is somewhat more readily soluble in spirit of 78 per cent.; and is abundantly soluble in spirit of 35 per cent. Strong alcohol precipitates it from its aqueous solution.

The solvent properties of the aqueous solution upon silver salts are well known. It dissolves the chloride, bromide, and iodide of silver, with readiness, converting them into the corresponding potassium compounds, and the double cyanide of potassium and silver. It is of great use in fixing collodion pictures, but is not adapted to positives on paper, as its action is too energetic upon silver, in so finely divided a state as it exists in the dark parts of the paper print. A weak solution of it is very valuable for fixing collodion positives, as it leaves the silver in a brighter and more lustrous form than when hyposulphite of soda is used. Many of our best operators are also in the habit of employing it for fixing negatives, especially when an iron developer is used in preference to pyrogallic acid. A convenient strength for the fixing solution is ten grains of cyanide of potassium to the ounce of water: this may be used over and over again, as it even seems to slightly improve after it has taken up some silver salts. As the commercial salt contains a large, but variable, quantity of carbonate of potash as impurity, and the above strength for the solution has been calculated for the pure salt, it will be advisable to perform a brief assay of its strength previous to making any quantity of fixing solution if required for particular purposes. The details of this assay will be presently given. When fixing with cyanide after an iron developer, care must be taken to wash all the latter solution well off before the cyanide solution is applied, otherwise the reaction between the iron and cyanogen compound produces prussian blue, which will be precipitated all over the surface of the picture. It will be likewise convenient to employ a vertical fixing bath for the cyanide in preference to pouring it from a jug or measuring glass, as owing to less surface being exposed in the former case, the solution will not so readily decompose, nor will the room smell so strongly of hydrocyanic acid. After fixing with cyanide of potassium, the plate requires less washing than if hyposulphite of soda had been used; and if it be required to intensify the picture by a subsequent treatment with pyrogallic acid and nitrate of silver, the surface will be left in a more favourable state for this operation than if hyposulphite had been used.

Cyanide of potassium is a very excellent agent for removing silver stains from the hands or clothes. Moistening a lump of the salt, and rubbing the mark with it, will frequently be sufficient. If, however, a stronger means is required, a solution composed of

Cyanide of potassium	... ...	100 grains
Iodine	... ...	10 „
Water	... ...	1 ounce

may be used with advantage. In any case the part from which the stain has been removed must be subsequently well washed with water.

Cyanide of potassium has remarkable solvent powers upon many metallic bodies, forming potash and a double salt of the metal and cyanide of potassium. It dissolves, in this way, zinc, iron, copper, and nickel, even when not in contact with the air; hydrogen being evolved. Other metals, such as cadmium, silver, and gold, are only dissolved by it when air can have access to it, the presence of oxygen being necessary. It has no solvent action on tin, mercury, or platinum.

In the chemical laboratory cyanide of potassium is of great use, owing to its energetic reducing properties. When heated with a compound, rich in oxygen, such as chlorate or nitrate of potash, it detonates with violence; when fused with many metallic oxides, it reduces them either to the metallic state, or to a lower oxide.

The value of commercial cyanide of potassium, or the quantity of the pure salt which it contains, may be very readily ascertained in the following manner:—It has been found that one equivalent of nitrate of silver, dissolved in water, requires exactly one equivalent of cyanide of potassium to completely precipitate it; and when thus precipitated, it takes exactly another equivalent of cyanide of potassium to redissolve the precipitate at first formed.

A solution must therefore be prepared by dissolving 170 grains (or one equvalent) of pure nitrate of silver in 10,000 grains of water. Each 100 grains of this will therefore contain 1·7 grains of nitrate of silver, aud each 10 grains 0·17 grains. This solution should be prepared with great care, and being properly labelled, preserved for future use in a dark place. When an assay of cyanide of potassium is required, weigh out very carefully 13 grains of the salt under examination, and dissolve them in a small flask in one ounce of water (the exact quantity being immaterial); now measure out 1,000 grains of the standard silver solution, and place it in a tall, narrow 1,000-grain burette properly graduated. Pour from this into the cyanide solution 100 grains of the silver test, and well shake the flask. The precipitate at first formed will probably dissolve readily; then add a little more of the test solution, shake it up, and observe again. Continue adding silver in this way until the precipitate seems to dissolve with some difficulty, when the silver solution must be added with some care, drop by drop, until at last a point is reached at which the addition of a single drop more causes the formation of a permanent precipitate. If the 13 grains of cyanide of potassium were quite pure, this point would be reached exactly at the pouring in of the last of the 1,000 grains of test solution; but we will suppose that an impure cyanide is under examination, and that only 780 grains of silver solution were required to cause the first appearance of a permanent precipitate. The cyanide would, in this case, be evidently impure, and the amount of impurity would be shown by a simple rule of three sum.

as 1,000 grains of test solution.	:	100 per cent. of cyanide of potassium.	: :	780 grains of test solution.	:	78·0 per cent. of cyanide of potassium.

The cyanide under examination contains therefore 78 per cent. of pure cyanide of potassium. The remaining 22 per cent. being impurity.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Invention.—"That property, by virtue of which anything is *originated*." The arrangement and combination of models is that part of invention to which photographers can best lay claim; but the selection and treatment of a view, &c., may also possess a very legitimate claim to be called inventive.

Keeping.—In accordance with the laws of harmony. If the middle and extreme distance should not display such gradations of tone, &c., as may be consistent with the expression of aerial perspective, there is a want of keeping, or in other words, of air and space, or relief. Again, if one part contrasts too violently with its neighbour, there is a want of keeping, and the same will be said of that portion of a picture which does not fall into its proper place as part of the whole, or is isolated and cut off from the rest by undue prominence.

Keeping Down.—The extremes of light and dark, being more prominent than intermediate tones (although, of course, even this must, to some extent, depend upon the ground which they appear on), are said to be kept down when rendered less black or less white. The subordinate parts of a picture, therefore, should not obtrude upon the spectator's sight from either the one or the other cause, but be *kept down.*

Middle Distance.—The central portion of a landscape.

Model.—Every object from which the artist by imitation produces his work, whether living or not, is thus called; but the term more frequently and absolutely implies the men or women whose forms are represented. A good model is a most valuable acquisition to the painter, but is even more valuable to the photographer, inasmuch, as the latter is far more dependent upon his model than the former for his best effects. The photographer will be apt to find the artist's professional model somewhat difficult to manage, because he or she has been educated rather to express the desired feeling by assuming a certain pose, than by working upon the feelings until they find expression in both attitude and face. Models from the stage, on the other hand, are apt to betray too palpably the source of their education, and convey au effect which is termed "stagey."*

* Of course I exclude from this assertion such glorious actors as Fechter reprepresents, whose acting cannot be too carefully studied by the artistic painter or photographer. I shall never forget his Hamlet!

A good imaginative and impulsive model, whose feelings are capable of being wrought up to the desired pitch by the mere reading of the passage you desire to illustrate, the narration of an incident to be represented, or the description of such a feeling or passion as is to be expressed, will be best for the photographer's purpose. It is astonishing how much may be done by these means. A few days since I had a young lady from one of the theatres with me as a model. The expression I desired was that of eager joy. In vain I posed, and posed, and posed again. I got a very nice and pleasant smile, a charming pose, but not what I wanted. At length, in a fit of impatience, I burst forth (earnestly, or I should only have been laughed at) with a description of a brigand's wife, whose dearly loved husband had departed upon an expedition of great danger, checking the rash desires of his brave young spouse, and refusing her permission to accompany him before he went away. You, said I, are this wife, the hour at which you expected your husband's return (here my operator brought up the plate in the dark slide) *so* anxiously looked for, has come and *gone*. Oh! can he be dead, will he never more return! These are the sickening thoughts which dim your anxiously watching eyes as you bend over the rock. Suddenly there is a well-known shout from the rocky heights behind. Your head darts round, joy flashing from your eyes like lightning from a stormy cloud, and there, leaping from crag to crag, alive, and rich with booty, you see your——that's it; keep that expression! one, two, three, and so forth (on goes the cap). Hurrah! bravo! I'm sure we've got it!" And so we had, and the photograph is now on my easel as the groundwork of a painting just commenced. I should never have got the expression I wanted any other way, although it may be thought a somewhat comical method of going to work. That photography, by such, or similar means, can pourtray things generally attributed rather to the imagination of the painter than to that of the model, Rejlander's works can prove. If you have a copy of "The Disciple," a picture of Rejlander's, described by me at page 302, vol. iv, and an engraving from a painting by Etty, bearing the same title,† and will compare them, you cannot fail to acknowledge the superiority of the former over the latter.‡ The photograph is full of feeling and indicates its meaning at once, while the engraving is a mere profile study of a head to which any other title might be as justly applied. I intend to get a copy of both the engraving and the photograph to hang side by side in my study.

The Nude.—An artist's study of the undraped figure may be very materially aided by the photographer. Many of the positions in which models are placed being intended to bring certain muscles into play, and these speedily becoming relaxed, it is only by the aid of memory, and frequently repeated sittings from the model, attended with all the inconvenience and trouble of obtaining precisely the same pose again and again, that each study is at length brought to a satisfactory conclusion. Of course, in draped figures, the difficulty is still as great from the changing of the folds. Photographs of nude models are, therefore, especially valuable to painters, and most of our best men now execute such as aids to artistic study. For the practice of this branch of the profession a soft, even light is required, for which a well-arranged collection of blinds and reflectors of different reflective powers will be essential.

Offskip.—A term not frequently used, indicating that portion of a landscape which recedes from the foreground.

Outline.—The conventional line which is used by draughtsmen to indicate the boundary of vision. A thing unknown to good photographs, although sometimes visible in bad ones.

---

† An engraving from this painting was published in the *Art Journal*, but I forget in which volume.

‡ I am told that a print from this negative—looking suspiciously like a spoiled one—is at the Birmingham Exhibition, and that it is so strangely altered by over-printing that many of its chief beauties are lost, and the expression itself suffers lamentably. If this is true, it is very much to be regretted.

ON THE CAUSES OF FAILURE IN THE WET COLLODION PROCESS.

By Professor Martin, of the College of Sainte-Barbe.

In this paper I propose to trace the causes of failure in the wet process, and the means of avoiding them.

The first condition to be fulfilled, is that of well understanding the nature of the collodion, and the elements of which it is composed. I have little to say of the ether, which may be obtained sufficiently pure and rectified at 62°; when newly prepared it is slightly alkaline, and has not been exposed to the action of light in a bottle not quite filled.

The alcohol I employ is that marked 40°, and is easily obtained.

The cotton exhibits the greatest variations, due to the conditions under which it is prepared.

There are four varieties of nitric cotton; viz.—

1st. Cotton of five equivalents of hyponitric acid (fulminating cotton); it dissolves only in methylacetic ether; the resulting solution after the evaporation of the ether, is a pulverulent deposit, which has no photographic application.

In a mixture of ether and alcohol this cotton appears at first to dissolve, but upon being allowed to repose, it all falls to the bottom of the vase in a gelatinous form.

2nd. The cotton of four equivalents of hyponitric acid (soluble cotton), is the true photographic cotton; it dissolves in methylacetic ether, and in a mixture of ether and alcohol; this latter solution, upon evaporation, leaves a transparent film more or less tenacious, according as the quantity of ether is lesser or great in the mixture of the two liquids.

3rd. The cotton of three equivalents of hyponitric acid (powdery cotton), soluble in the same liquids as the preceding, is also soluble in acetic acid, and in diluted nitric acid. The film it leaves upon evaporation is always opaline, and is deficient in tenacity, both from the nature of the cotton, and also because this cotton requires in the mixture of ether and alcohol a greater quantity of alcohol than the cotton of the preceding quality.

4th. The cotton of two equivalents of hyponitric acid is soluble in water, and does not leave a coherent film on the glass; immersed in water, this film disappears completely.

These varieties of cotton are seldom obtained with such decided characteristics as those about to be described; generally, they are mixed in variable proportions in the products met with in commerce.

In 1852 I described a method which permits the obtaining with certainty a cotton entirely soluble in the mixture of alcohol and ether; since that date this method has been followed by one of our principal chemical manufacturers, who assures me that he can always make sure of obtaining the best results.

Since that date, Mr. Hardwich has profoundly studied the nature and manufacture of soluble cotton by the mixture of sulphuric and nitric acids. I have carefully repeated all his experiments; at first I experienced failure due to the monohydrated nitric acid I employed being a little too rich in hyponitric acid; but when I recognised that it was this latter acid which is the real agent of transformation of ordinary cotton into nitric cotton, I completely succeeded. the different varieties of cotton that I wished to study in the manner pointed out by the English chemist.

The presence of the first variety of cotton (fulminating cotton), has no other inconvenience than that of leaving us ignorant of the actual quantity of soluble cotton introduced into the collodion, and of giving it a tendency to blister.

The third variety (powdery cotton) which gives an opaline film, and is deficient in tenacity, may be easily separated from the soluble cotton, by beating the latter a little between the hands, and blowing upon the tufts before introducing them into the mixture of alcohol and ether.

The fourth variety, soluble in water, is only met with in cottons badly washed, but *it is produced in collodion already prepared, when this latter contains alkalies.*

The alkalies have the property of removing from the dissolved cotton a certain quantity of hyponitric acid, and of causing it to pass successively from the first to the fourth variety; to their presence is due the sole alteration collodion can undergo with age in well stoppered bottles, and not exposed to the light.

The last constituent element of collodion is the soluble iodide added to it.

The iodides have a great tendency to combine with a certain quantity of the oxide of the same base, so as to form an oxy-iodide.

The oxy-iodides soluble in water are decomposed by alcohol of 40°, if the oxide is soluble in this liquid; this takes place with cadmium and zinc; potash being soluble in alcohol, the oxy-iodide will be dissolved and the potash will react upon the cotton to cause it to undergo the alterations mentioned above. Thus the collodions iodized with iodide of potassium are always instable, and the photographer desirous of avoiding every source of failure ought to *absolutely proscribe it from the composition of his collodion, as well as every iodide with oxide soluble in alcohol.*

The iodide of ammonium so easily loses its excess of ammonia in becoming yellow, that it may be said to be without inconvenience.

The preceding facts being well known, I make my collodion in the following manner:—

In 150 cubic centimètres (5¼ f. oz.) of alcohol at 40°, dissolve 5 grammes of iodide of cadmium (77 grains) and 6 grains of bromide of cadmium, if bromides are employed. Allow the mixture to subside, when a gelatinous deposit of oxide of cadmium precipitates, then filter and add 350 cubic centimètres (11⅓ f. oz.) rectified ether at 62°. If the ether is not acid, the mixture will remain colourless; by means of a drop or two of alcoholic solution of iodine, I give to it a pale straw colour, then dissolve in it 5 grammes (77 grains) of cotton entirely freed from pulverulent matters. After the lapse of a few minutes, shake the mixture, then leave it to settle.

I do not pretend to give absolute proportions, but a certain mode of preparation. The proportions vary a little in the practice of operators, some prefer a thin collodion, others a thick. The aim of the method prescribed above is to separate the iodide from the oxide it contains, which produces *fogging* and grey tones, and afterwards instability by its reaction on the cotton.

Note.—If the mixture of iodide of cadmium and of a slightly yellow iodide of ammonium be employed, the addition of free iodine becomes unnecessary.

I employ crystallized nitrate of silver for my bath, and if necessary, dry it in a porcelain capsule in a *bain marec.* The fusion of nitrate of silver is always a dangerous operation for the success of photographic processes, in consequence of the possibility of a slight decomposition by the organic matters introduced into the crucible. From 40 to 50 grammes of nitrate of silver are dissolved in 250 grammes of water, into which some drops of a filtered solution (alcoholic) of iodide of cadmium are put, so that there remains a slight excess of non-dissolved iodide of silver; then add the 250 grammes of water necessary to complete the bath; a fresh portion of the dissolved iodide is precipitated; the bath is filtered twice through the same filter, and is then ready for use.

The developing agent must fulfil several conditions:—

1st. It must act upon the nitrate of silver of the film only in those places impressed by light, and not in the substance of the liquid.

2nd. It must penetrate the film so as to act wherever the light has exercised its action.

3rd. It must not begin to act until after one or two seconds, so as to permit the operator to pour the liquid on the plate without leaving stains.

Employed in the following manner pyrogallic acid fulfils these conditions very well.

Dissolve 1 gramme of pyrogallic acid in 15 cubic centimètres of crystallizable acetic acid, and 5 cubic centimètres of alcohol at 40°. This solution will keep a very long time in the dark, and is a good provision for a photographic excursion.

When required for use, add 5 centimètres of this solution to 100 centimètres of water free from lime. Distilled water is not necessary when we first satisfy ourselves by experiment that the solution does not become yellow in the course of a few hours.

Prepared under the preceding conditions this solution serves to completely develop a proof without the appearance of that *black mud* which is due to the reduction of the silver in the body of the liquid and acts to the detriment of the image.

If it be required to strengthen a weak negative, we employ the same liquid, to which a few drops of nitrate of silver, of the strength of 5 per cent. has been added.

Certain conditions of light require operators to develop with sulphate of iron.

In this case I dissolve on the one hand 100 grammes of sulphate of iron in 250 grammes of water; and, on the other, 5 cubic centimètres of acetic ether, and 10 cubic centimètres of alcohol in 250 grammes of water; I add the second solution to the first, and employ the mixture as a developing agent.

For instantaneous negatives I substitute for acetic ether, the nitric ether of commerce, which alcoholized nitrous ether. In this case the solution of iron becomes very brown, and gives a deposit in the course of four-and-twenty hours; but it is only necessary to filter it.

These iron baths, filtered at each operation, may serve many times, and if it be remarked that they give an abundant precipitate in their mixture with the nitrate of silver on the plate, it is because the quantity of light is too feeble for the iron bath; the latter must then be diluted with its bulk of water before being employed.

The fixing is effected with a saturated solution of hyposulphite of soda, in the same manner as the picture is developed.

ON MEASLES; ITS DIAGNOSIS AND TREATMENT.

Think not, gentle reader, I am a learned M.D., about to give you a long lecture upon the complaint of childhood, with which all of you are more or less familiar: no, rather I am about to hold a little conversation with you on a complaint which, to see the many letters addressed continually to the various Journals of our most fascinating art, seems to be the plague and trouble of your every day existence!

I have divided the subject, as you perceive above, into two parts, first, What is really known by the name measles, its character and appearance? and, secondly, What is the best treatment for it?

In answer to the first question; from what I have been able to collect from dealers in albumenized paper, there seems to be two different appearances called by the term measles; one, where, when the paper goes into the gold-toning bath it seems as if its surface was in a flocculent state, minute raised fibres receiving less albumen than the hollow parts, consequently toning first, so that if it be pushed sufficiently far to get the red, slowly toned parts subdued to a purple black, the fibrous parts will have gone into a cold leaden grey, thus giving a flat mottled appearance to the fixed picture. I am now speaking of toning by the common neutral, or slightly alkaline gold bath of chloride of gold and carbonate of soda. The second description, which is generally the result obtained by beginners, or "penny-wise" operators, is a poor, weak, foggy sort of print, without any strength or contrast, it is seen in the pressure-frame before it goes into the gold, and turns rapidly grey in the toning, and when fixed and dry has no sharpness, and seems as if it had been sprinkled all over with sand. This is the result of either starting with too weak a silver bath, or not making sufficient allowance for the amount of silver decomposed in it; some persons are hardly aware of the great amount abstracted by the salt in the paper, besides the mere liquid dried on its surface; from calculations I have made I find, as near as possible, 24 grs. are consumed in each sheet of 22×18, besides one-sixth of an ounce of liquid of the original strength; for the new toning processes the bath ought to be at least 70 grains to the ounce, so that it will be much the best to start with 80 grains; every three sheets will take half an ounce of liquid containing 40 grains, besides 72 grains decomposed by the salt; we have, therefore, only to make a solution of 112 grains to half ounce of water, and add after every three sheets, or one-third of that to every sheet, to keep up the original strength of the bath. This weak effect of picture is also produced by not stirring up the silver after every piece is taken off it; supposing the liquid in the Wedgwood dish to be ¼-in. deep, if two or three pieces are put on and carefully taken off, the silver is decomposed from the surface as well as the liquid abstracted, and from the high gravity of the nitrate, the upper stratum is at length almost water; a piece of glass about three inches wide, and long enough to take hold by, passed backwards and forwards through the liquid without making bubbles will do the job, and it can rest on the edge of the dish until the next sheet comes off.

We shall now proceed to discuss that which is generally known by the name of measles, which we first mentioned above, and to answer our second question. What is the best treatment for it? and here I shall be met with the counter question, Why not find a preventive for it? as prevention, &c., &c. True; but after all the inquiries I have made, it seems impossible to find a certain remedy for preventing it altogether; rolling the sheets before albumenizing, care in the manipulation, drying in hot air, and leaving a short time on the liquid—all go a great way; but still it will occur sometimes, in spite of the utmost care and skill, so that our only recourse is to find out the best method of treating it so as not to be disappointed in wasting our results. It certainly stands to reason, that the best remedy would be to prepare a bath for toning that shall tone to a certain good colour and go no further, but allow the slow-toning parts to catch up tho first tòned, and so make the whole uniform; can such be done? yes, the whole secret is to discard the plain alkaline bath altogether, and to use an organic salt of gold, as introduced by Mr. Hardwich, either acetate or citrate, I prefer tho latter; there is no occasion, however, to use the amount recommended by that gentleman. One grain of citric acid to every grain of chloride of gold, neutralized after mixing with carbonate of soda, will be quite sufficient to produce the effect required; the acid will keep any length of time in solution by putting a small piece of camphor, the size of a pea, into the bottle; it is convenient to keep the acid and soda in solution in separate bottles, both of the strength of one grain in half a drachm of water, or 16 grains to the ounce. It must not be supposed, however, that without care this will always get rid of the measley effect; the paper must be watched while toning, and removed, if very bad, directly the purple tone is reached in the quickest toned parts, never mind the measles looking bad in this stage, it will disappear after fixing and drying; the great fault of those who complain is, they almost always *over-tone* their prints; in endeavouring to get the red mottles toned they go on until the ground colour is completely grey, whereas, had they stopped as soon as the purple was just reached, the print would have been of a rich warm tone, and the measles hardly perceptible; the organic salt of gold has, however, great power in giving depth and richness, hardly ever, without pushing very much, going into the cold stage, so that it is very preferable to the normal solution. There is a great mistake in piling on the gold as some are so fond of doing, most of our first-rate photographers cannot bear it; witness the works of Roger Fenton, Francis Bedford, and Russell Sedgfield, the two last gentlemen asserting that to get an inky black with a heavy deposit of gold, is burying the fine details in the shadows of these pictures in *mud*.

I can fully assert, from having worked very largely for for some time with the last of the above gentlemen, that the whole secret by which their prints are so justly and deservedly admired, is that they follow the invaluable maxim of using "plenty of silver, and of sparing gold."

Francis G. Eliot.

MODIFIED COLLODIO-ALBUMEN PROCESS.

By H. Petschler.*

After a few remarks explaining his reasons for a full and detailed statement of the process, he proceeded—

To begin, prepare tho following solutions:—

NITRATE OF SILVER BATH.

Nitrate of silver crystals	1 ounce,
Distilled water	11 ounces,
Iodide of silver	to saturation,
Acetic acid	a few drops.

To saturate with iodide of silver: dissolve the one ounce of nitrate of silver first in three ounces of distilled water: add to this three or four grains of iodide of potassium. The whitish precipitate formed is iodide of silver. Stir it, and it will presently dissolve, or nearly so. Now add the remaining eight ounces of distilled water, to make up the eleven ounces, as in the above formula. This will cause a re-precipitation of part of the dissolved iodide of silver. Let this milky-looking liquid stand to settle for some hours, and then filter through clean blotting paper, and add the few drops of acetic acid, so that the bath is slightly acid. It is then fit for use. It should be frequently filtered during usage.

PREPARED ALBUMEN.

Tho white of	6 eggs,
Distilled water	3 ounces,
Chlorido of sodium (common clean kitchen salt will do)	18 grains,
Liquor ammonia	60 minims

Dissolve first the salt in water, add the ammonia, and then mix with the albumen. Shake or beat it up into a quick froth. Let this stand a day or so, and filter the liquid formed through a sponge pressed loosely into the neck of a funnel. Keep it in a bottle corked up.

Instead of the three grains chloride of sodium to the ounce, as in the above formula, I sometimes use—

The white of	6 eggs,
Distilled water	3 ounces,
Chloride of sodium	15 grains,
Bromide of potassium	3 grains,
Liquor ammonia	60 minims.

The introduction of the bromide, I believe, makes the pictures softer, but the development is a little longer. With an iodide it takes a still longer time to develop.

To flow the albumen over tho plate without getting air-bubbles, use two beaker glasses or clean cups which will pour well; place a funnel with its spout broken off on one glass, so that it will reach nearly to tho bottom, and press a sponge loosely into the funnel. When pouring the superfluous albumen back from the plate, always pour into the funnel, changing it from glass to glass, as the filtered fluid is being used.

Collodion.—I have succeeded best with a good positive collodion mixed with some old negative; but any good negative or positive collodion itself seems to answer well. An ordinary negative collodion diluted with ether works very well. Of course, whatever collodion is used should be of a known good quality. It does not require any peculiar kind; but if it is not good no process will succeed with it. I have not met with any yet which has not given me tho desired density, with proper development. Always have plenty at hand when working. When many plates are prepared at a time dilute some collodion in a separate bottle with ether, and keep adding it to that in use as it gets too thick, taking care to shake it up before using it again.

PREPARATION OF THE PLATE.

Before commencing to operate have everything requisite

* Abstract of a Paper read at a Meeting of the Manchester Photographic Society, June 5, 1861.

prepared and placed in the places where most convenient to handle. Do this, if possible, an hour or two before beginning, in order that any dust caused by your preparation may first settle. Filter the silver bath, if required. Have plenty of *clean* blotting paper at hand, ready cut and folded, and a clean towel to wipe the hands with; but do not knock this about much whilst using, as the lint is apt to fly from it. Clean and polish your plates well. This should not be done in the operating-room, or at any rate not there immediately before the preparation of the plates. See that no dust is flying about whilo coating the plate.

Warm the plate slightly to a littlo above tho temperature of the room. Get firm hold of it by means of a clean pneumatic plate-holder; but let this holder not bo colder or warmer than the plate, else a ring is formed in the film. Brush it over with a clean, flat camel-hair brush to remove dust, and coat it with collodion. When well set—say in a few seconds, longer or shorter, according to existing temperature—detach the plate from the holder by getting hold of it firmly with your thumb and forefinger by one corner only; and, whenever the plate requires handling during the manipulation, always confine yourself to this one corner: never get hold of it by the sides. Stains are very liable if the plates, especially when wet, are handled too much. When the collodion is well set, dip the plate into the nitrate of silver bath, with one even continued motion. I use a wooden well bath for large plates, well varnished inside and out with shellac. Shake up the collodion in the bottle just used, so that it may be equally mixed again for the next plate: this will, to a great extent, prevent cloudy appearances in the film.

In a minute or so lift the plate in the bath up and down a few times to remove the apparent greasiness from the surface. Leave it in the bath four or five minutes, and give a few more up-and-down movements. Then remove into a dish filled with clean common water, but not into running water.

Coat another plate with collodion, and place into the silver bath as before.

Take the first plate out of the water, always getting hold of it by the same corner as at first; place it on the plate-holder, and pour water over it gently and evenly, until the apparent greasiness on the surface disappears, not longer. This washing should not be too much, as I have good reasons for believing that if too much of the nitrate of silver be removed, it will cause uneven sensitiveness on the film. The amount of water used for this washing is immaterial: it may be used either direct from the tap or from a vessel, but it should be done gently and evenly. I have a flexible india-rubber tube, about half-a-yard long, fixed to my water tap. Holding the plate in one hand and the tube in the other, I play on the surface of the plate gently two or three times all over, when the water will flow evenly down over the glass. Drain whilst in your hand for half a minute or so; in the meantime give the second plate in the silver bath a few up-and-down motions.

Now pour the albumen on the plate, sufficient to cover the surface, without spilling, in one continued wave from end to end, on and off twice. Do not let the wave stop until it gets to the opposite end to the one poured on, else the stoppage will cause a line in the negative. Drain in your hand for a few moments, until the bulk of the albumen is dropped off; then place on one corner, on clean doubled blotting paper, face side to the wall, and wipe the back with some blotting paper. Take care not to let the scratching against the wall cause any dust to fly: in the wet state the film soon catches it up and would cause spots in the negative.

Now take the second plate out of the silver bath and proceed as before, until as many plates as you desire to prepare at the time are finished.

When surface dry or nearly so, say in about an hour, bake the plates, by holding them either before a brisk red fire, or in an oven, or on a hot water bath. I use a tin box with two flat sides, the ends conical shaped, with a narrow base. At the bottom of each flat side is a ledge for the plates to rest on. At the top of one of the corners is a spout. This is nearly filled with water and placed over a Bunsen burner to heat. The water need not be quite boiling, but nearly so—say between two hundred degrees and boiling point. I keep them on this to bake for five or ten minutes.

The only thing necessary now is to wash them well in clean water, and they will be ready for the camera when dry.

After the baking the plates are comparatively insensitive to light, and may be kept in boxes for a very long time, until required for re-sensitizing. A short exposure to a weak diffused light will not do them much harm. However, where it is not inconvenient, I should recommend them always to be kept in the dark; but, in case they be, by chance or by necessity, exposed to light, it is necessary to give a longer exposure in the camera than usual. In this case the negative will acquire its proper intensity before any injurious fogging may appear.

If the plates are wanted to be finished off at once after the baking, they are placed in a dish of common water, running if possible, before they are quite cool, and left in there from five to ten minutes or longer, if convenient; then fixed on the plate-holder and well washed under the tap; and finally (if at hand) flushed over once or twice with distilled water. Let them drain in your hand a few moments, and place on one corner on clean double blotting paper, face side to the wall to dry. After a few minutes change the wet blotting paper for some fresh, else it may cause foreign matter to be drawn up on to the film by capillary attraction. When dry they are ready for exposure in the camera, but do not put them away till they are quite dry. In this state they will keep good and sensitive for months.

When the plates after the baking are kept before being sensitized in water, I should recommend them to be warmed again before the final washing. This will keep the film firmer on the glass.

The exposure in the camera required is about the same as some other dry processes—say about three to thirty minutes for stereoscopic pictures, six inches focus, quarter-inch stop; and about six minutes to one hour for eleven by nine inches pictures, half-inch stop, according to light and subject. This must be learned by experience. When convenient, I should recommend a long exposure, as the pictures in this case are less dangerous to develop.

DEVELOPMENT.

Prepare the following solutions:—

Pyrogallic acid	3 grains,
Citric acid	1 grain,
Distilled water	1 ounce

Filter if not clear.

Nitrate of silver	10 grains,
Distilled water	1 ounce.

Filter if not clear.

Fresh nitrate of silver must be used for this solution, not old silver baths. Also—

Protosulphate of iron	8 grains,
Acetate of soda	4 „
Acetic acid	20 minims,
Distilled water	1 ounce.

This last-named developer was recommended to me by a friend for wet plates. I find it answers well for the dry process.

The development is of great consequence, and in order to get soft and vigorous negatives, it should be begun with very little silver, not increasing that until all the details are well out.

The following mode I find the best:—Hold the plate by means of a plate-holder firmly in the hand, moisten the surface all over quickly and well under the tap or in a dish, and flush it over with distilled water. Take of the strong three-grain pyrogallic developer, as per formula, sufficient to cover the plate well, and pour it on and off several times; then add to the ounce of developer in the cup three to four drops of the ten-grain nitrate of silver solution, and continue pouring it on and off the plate, thus keeping it constantly in motion. After some minutes the picture will appear: first the sky and high lights in the body of the picture, gradually followed up by the less and still less illuminated parts. Continue developing with the same solution until all the details are perfectly out; then take some fresh pyrogallic solution, and dilute it to about half its strength with distilled water, and add about half a drachm of the ten-grain nitrate of silver solution; with this continue developing until the required density is attained. If this should not bring out the intensity, dilute some fresh pyrogallic solution still further, say to about quarter its strength, and add a drachm or two of the ten-grain silver solution: this has never failed in my hands in bringing out the desired intensity. Should the picture give signs of decided fogging before the proper density is acquired, or should it make its appearance with great vigour, quicker than usual—in fact when the plate gives unmistakeable signs of much over-exposure—then dilute the developer at once considerably, and add plenty of silver;

this will soon darken the high lights, whilst the shadows will follow but slowly. Experience only will teach the operator how to humour the negative. Any reasonable exposure too little or too much may thus result in a good picture by slow or rapid development; but I would caution you against a too rapid development, as the resulting picture is likely to be hard. The best way to know when the silver in the developer should be increased is when, looking at the surface by reflected light, the strongest shadows in the negative appear to begin to fog. The pyrogallic should then be weakened and the silver increased, not before.

Another mode of development which I have been very successful with, and which promises to be very useful, especially when pictures have been under-exposed, is, to begin with the protosulphate of iron and acetate of soda developer, as per formula above, commencing with little silver, and increasing it according to exposure. When the details are all out, and the negative gives signs of fogging before the desired density is obtained, then change the developer. Take of the pyrogallic solution, diluted to about one grain to the ounce, and add half a drachm or more of the nitrate of silver solution. This will soon darken it. With this iron and acetate of soda developer very soft pictures may be obtained, and a shorter exposure is necessary. Mixed with the silver it soon gets muddy, and should be changed when it gets too dirty.

By a subdued yellow light, the appearance of a good negative, before fixing in the hyposulphite of soda, should be almost black or dark brown in the high lights, and fogged in the shadows. When the hyposulphite has afterwards dissolved out the iodide of silver, it will appear lighter and more transparent. A good negative should not have any perfectly transparent places like the glass itself. A slight fogging in the shadows, with detail and gradation of tone up to dark brown in the high lights, make rather slow printing negatives; but the best pictures are obtained from them.

When the development is carried far enough wash the plate in common water, and place it in a solution of hyposulphite of soda: say—

Hyposulphite of soda	3 ounces,
Common water	20 ounces,

until the yellowish green iodide of silver in the plate is all dissolved out. Then wash well for a minute or two under the tap, so that no hypo may remain in, and dry either spontaneously or by gentle heat. If the film should wrinkle after the fixing and washing, dry spontaneously: it will then adjust itself.

When dry, examine it by daylight, and see whether all the iodide of silver is out of the film, and whether the negative is dense enough. If all right, then varnish it.

If the iodide be not all out, it may be replaced in the hypo. If it be not dense enough, and the hypo having been previously well washed out, it may then be strengthened by a very weak solution of pyrogallic developer and a ten-grain solution of silver mixed half and half. This must be done very quickly, and with great care, as the negative is sometimes liable to darken very soon, and too much.

Lastly, I will enumerate the most important points necessary for success in the process.

1. Let the glass be of the same temperature or above that of the atmosphere of the room when coating it with collodion. This will, to a great extent, prevent blisters.

2. After taking the plate out of the silver bath do not wash too much, but merely until the water flows evenly over the glass. This will ensure even sensitiveness of the film.

3. Wash well after the baking, so that all the excess of chloride of sodium in the film be dissolved out. The more they are washed the more sensitive they are likely to be.

4. Give plenty of exposure in the camera.

5. Develop slowly, commencing with a strong pyrogallic solution and little silver, gradually weakening the pyrogallic and increasing the silver.

THE SOCIETIES, AND THE EXHIBITION OF 1862.

We have not yet learnt the decisions of the whole of the societies regarding this question; so far, however, they are unanimous in upholding the position of the Parent Society. We extract the following reports from the organ of the societies named.

Birmingham Photographic Society.

A special general meeting of the members of this Society, to which the public were admitted, was held in their rooms at the Oddfellows' Hall, Temple Street, Birmingham, on Tuesday evening, the 25th ult., to consider the position which has been assigned to the art of photography in the Exhibition of 1862, and to arrange for a memorial, and to determine as to the course which, in the opinion of the Society, ought under the circumstances to be pursued. Mr. W. B. Osborne, Vice-President, took the chair, and there was a very fair attendance.

The Secretary read the circular convening the meeting, and the correspondence that had taken place between the Council of the Photographic Society of London, and the Commissioners of the International Exhibition of 1862, as to the position assigned by them to the art of photography in their regulations.

The Chairman, who briefly opened the discussion, contended that a painting and a photograph were equally the result of the genius of the artist, as exhibited through the instrumentality of such tools as might be placed in his way, whether it was by the colours, brushes, and mahl stick in the one case, or by the lens, camera, and chemicals in the other; and, that this being so, they ought to be placed on an equal footing in the International Exhibition.

Several other gentlemen spoke to the same effect; after which

Mr. Brown, Hon.-Sec., proposed—"That this meeting is of opinion that the classification of photography by the Commissioners in their programme of regulations for the proposed International Exhibition of 1862, is both unfair, discourteous, and unjust; and, while they highly approve of the steps taken by the Council of the London Photographic Society, and the arguments used by it in the endeavour to induce the Commissioners to amend the said Classification, would urge upon all photographers the necessity of refraining from exhibiting their productions, or in any way taking part in the Exhibition, until a more fair and equitable position is assigned to photography as an art; and while this meeting cannot but deeply regret the course the Commissioners have taken, they would cordially join the Council of the London Society in presenting a memorial to the Commissioners upon the subject, or in any other course the Council may deem it desirable to adopt."

The resolution was seconded by Mr. C. L. Haines, and was put and carried unanimously.

Mr. Turner then briefly proposed—"That the most cordial thanks of this meeting be conveyed to the Council of the London Society for the praiseworthy position they have assumed in upholding the present important interests of the art of photography."

Mr. Burr seconded the motion, which was carried *nem. con.*

After the usual vote of thanks to the Chairman, the meeting terminated.

City of Glasgow and West of Scotland Photographic Society.

This Society held a special meeting on the evening of the 20th ult., in its usual place of meeting,—Mr. A. Mactear in the chair.

The Secretary intimated that the meeting had been specially called for the purpose of considering a circular and relative documents which he had received from Dr. Diamond, the Secretary of the Photographic Society of London, regarding the position which the Commissioners propose to assign to photography in the International Exhibition of 1862.

Several of the members present expressed their opinions on the question; all, however, fully concurring in condemning the doings of the Commissioners.

Resolutions were then passed, homologating the past acts of the Council of the Photographic Society of London; and the Secretary was instructed to write to the Secretary of that Society, thanking the Council of the Society for what they had done, and assuring them that the City of Glasgow and West of Scotland Photographic Society joined in the strongest remonstrance they could send forth against the *absurd, inconvenient,* and *unjustifiable* arrangement proposed by the Commissioners.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 3rd July, 1861.

It is no novelty to employ glycerine in the preservative processes for wet collodion, but from some cause or other its use has not been persisted in, and it seems to have been consigned to the tomb of the Capulets with the faded glories of honey and raspberry syrup. M. Gaudin, however, has attempted to resuscitate it. Considering that glycerine is unquestionably a substance capable of preserving the humidity of the collodion film, and of preventing the crystallization of the nitrate of silver, and its dissolving action upon the iodide of silver, he concluded that by the addition of a suitable quantity to the nitrate bath the desired result would be obtained.

A large quantity of glycerine may be added to the nitrate bath, as much as ten per cent. in volume, without the manifestation of any other result than a slight cloudiness, due to the precipitation of iodide of silver; but at the end of twenty-four hours a small quantity of black powder is deposited, and after filtration through paper, the bath deposits a fresh quantity. Collodioned plates sensitized in this mixed bath appear to be intact half an hour after being removed from it; but to develop the image it is necessary to immerse the plate again in the bath, before applying the developing solution, without which the sensibility will be found wholly destroyed; thus the presence of glycerine in the nitrate bath produces the expected preservative effect, but to the detriment of its sensitiveness. To appreciate the sensibility of the nitrate bath with glycerine, M. Gaudin, after placing the collodioned plate in a little apparatus with a card pierced with a pin-hole for a diaphragm, he left it while he went out for a walk; on his return he gave the plate two minutes exposure, the time usually required to obtain a visible proof. The collodion appeared intact and moist, but the sulphate of iron developing solution brought out only the sky. In operating again, after the plate had remained half-an-hour in the apparatus, it was exposed the usual time, with the diaphragm; again the collodion appeared intact, and after a fresh immersion in the nitrate bath, the sulphate of iron developed a very pure image as usual, less marked, perhaps, than it would have been with a bath free from glycerine.

Mr. Clarence Morfit has had the ingenious notion of reducing, by means of photography, a large scale accurately divided to the requisite dimensions for micrometric instruments. A scale of ten inches divided into inches and tenths of an inch, was by this means reduced to the length of half an inch, so that the smallest divisions of the micrometer correspond to the two hundreth part of an inch. This method is certainly the simplest and most economical yet employed.

Wooden baths for nitrate of silver solutions appear to present some advantages over gutta-percha or glass and porcelain; the former is so easily damaged by heat, and the latter are very heavy baggage and easily broken. Wood is light, strong, and not easily put out of shape and may easily be applied to the construction of baths of any dimensions. Some light wood, such as poplar or sycamore, which does not split when nails are driven into it, is best adapted for the purpose. It must be well dried, so as to absorb as little of the lac varnish with which it is covered as possible, for, in fact, the wood is only the envelope. It is rendered waterproof, and, consequently, there is nothing to fear from distortion by absorbing the nitrate or the moisture of the atmosphere, nor from the action of the nitrate of silver upon the iron nails. These latter can, therefore, be employed in great abundance, without fear of their being destroyed. If the nitrate solution should happen to reach them, they will be destroyed; but as the action will be slow no injury will result to the bath, the salts of iron are in no respect detrimental.

The thickness of the wood will, of course, vary with the size. Before being nailed together, the pieces should be coated with fresh, plain albumen; and, after being joined together, the wooden bath should be placed in an oven to coagulate the albumen, and afterwards left in a warm place for a day to prepare the wood for the reception of the varnish.

The varnish must be made with shellac dissolved in rectified alcohol, which is the only solvent that yields a uniform, transparent varnish. With ordinary alcohol, the varnish will be opaque, without consistency, and attackable by water. At first a coating of weak varnish is applied, and a second when the first is perfectly dried; and when this is dry, a quantity of varnish should be poured into the bath, so as to cover every part of the interior, then poured out, drained, and dried.

M. Martin suggests the following mode of colouring positive proofs on collodion, copied in the camera from negatives. A plate worked with wet collodion by the ordinary method is developed with diluted sulphate of iron; the developed proof is carefully washed, and before fixing it is covered with a solution of bichloride of mercury. Decomposition immediately ensues, giving rise to protochloride of mercury and chloride of silver; a small quantity of mercury set free fixes itself upon the silver of the picture. When carefully washed, a solution of cyanide of potassium or of hyposulphite of soda previously saturated with silver is poured over the plate; it is left to act for a few seconds, the traces of mercury adherent to the film decomposes the double salt contained in these solutions, and causes a precipitate of metallic silver in a finely divided state, which gives a very fine colouring to the picture. The operation is concluded by fixing in the ordinary manner, preference being given to hyposulphite of soda in a state of concentrated solution, and, after sufficient washing, the picture may be transferred by means of gelatined or albumen paper.

There appears to be a perfect stagnation in scientific discovery; learned bodies are exclusively occupied in the discussion of trite subjects, among which spontaneous generation, colouring matters from coal tar, and the composition of steel. The sudden appearance of a brilliant comet will doubtless relieve the present monotony.

M. Pelouze has made known a curious reaction with chloride of calcium. Acted upon by steam at a sufficiently high temperature, chloride of calcium is decomposed, producing a considerable quantity of hydrochloric acid. The transformation is so quick, that he was first tempted to believe that it offered a new process for the manufacture of hydrochloric acid on a large scale; but further experiments go to show that the production of acid was only abundant at the beginning of the reaction; that to maintain it, required the expenditure of a considerable quantity of steam, and consequently of fuel, so that the manufacture ceases to be economical.

Sulphide of carbon has lately been applied to the purification of oils with much success. It has a great affinity for fatty bodies, as may be shown from the fact that when the bones of which ivory black is made are treated in the usual manner, only five per cent. of fat is obtained; treated with sulphide of carbon, they yield twelve per cent. Immense quantities of soap are wasted in extracting grease from wool; treated with the sulphide, the operation is more efficacious, economical and expeditious. Oily seeds treated with the sulphide yield 10 to 12 per cent. more oil than by the old processes; besides, the oil is purer and entirely free from oleaginous matters, and requires no purification; besides, the oil contains more stearine and margarine, and consequently yields a harder and better soap.

The mode of operating is very simple: the fatty matters and the sulphide are mixed together in a closed vessel, and the sulphide allowed to filter off, carrying with the oil; the receiver is converted into a distilling apparatus; steam is introduced, the sulphide passes off, leaving the pure oil behind. The sulphide can be employed over again.

MODIFIED TAUPENOT PROCESS.

Dear Sir,—The favourable notice you were kind enough to take of the stereograms I sent you a few weeks ago, induces me to offer to the experiments of both yourself and readers what I consider a very important modification of the *Taupenot* process.

As I wrote you in my last, the hot water process, as indicated by Mr. Parry, gives me uniform success; its great advantages are, sensibility, cleanliness in development, and freedom of blistering, wrinkling of the film, &c. It struck me since, that the taupenot or collodio-albumen plates might be treated in the same way, and I am happy to say my supposition proved right, so that we may actually give a collodio-albumen plate its second sensitizing by one continued operation, NO INTERMEDIATE DRYING being necessary. My *modus operandi* is as follows :—

a. Cleaning, collodionizing, sensitizing in ordinary silver bath.

b. Thoroughly washing under a tap.

c. Covering with albumen iodo-bromised. Mr. Whipple's formula is excellent for this purpose, omitting the syrup, after which

d. Immediate immersion in a dish, filled with boiling, or nearly boiling water, taking care to let the water overflow the surface in continual waves. Having taken the plate from this bath, I keep it again for a few moments under the tap to clean the back, lowering the temperature to the mean of the second silverbath.

e. Giving the plate its final sensibility in the second silverbath.

f. Thoroughly washing under the tap.

g. Putting aside to dry in the dark. I use a large deal box, putting the plate on blotting paper, with its face to one of the sides, no harm ensuing, which is not the case in the Fothergill process. When I want to use them the following day I let them rest with the upper edge, for about half-an-hour, against a stone bottle, filled with boiling water, to ensure equal dryness, and as a result, equal development. The plates are really sensible; as a common rule, I give a long exposure—three or four minutes—in the sun, with a Lerebour's landscape stereoscopic lens; but to make a trial I gave a few only one minute exposure at seven o'clock in the morning, and got a good negative, without hardness, and with a transparent sky. So I suppose, that with the new Dallmeyer lens, a few seconds may suffice.

I develop with 3 grains of pyrogallic acid to the ounce, 1½ grains of citric acid; with addition of *very little* silver solution, of 27°. *Great rapidity* may be obtained by using gallic acid, with a little silver, and a few drops of a 5 per cent. acetate of lead solution, only the ensuing negative lacks strength. The collodion I use is very fluid, and contains bromide, in the proportion of two iodide to one bromide.

The second sensitizing bath contains *acetate of lead*. The negatives are remarkably clear, free from any fogging. Washing the plate with dilute gallic acid, after the final washing, following the sensitizing, I consider an improvement.

If the albumen has been used over and over again, stains are sure to make their unwelcome appearance, as I found from experience. So care must be taken to use only fresh solution.

By this somewhat lengthy communication I do not pretend to make a revolution in the collodio-albumen process, only I feel convinced that the working affords greater facility, and that the chief defects, as blistering and danger of unclean development, are done away with. And that these evils are very common, no practical operator will deny; and as a proof, I wish only to point to the many receipts for overcoming the first, and the information that any dirt arising from development may be wiped away by a wet brush of cotton wool.

I hope you will do me the favour of bringing my modification before the public, and giving it a few careful experiments yourself. I first intended to send it as a communication to the Manchester Photographic Society, in compliment to Mr. Sidebotham's valuable advice in your journal's first volume; but as this society holds no summer meetings, I prefer to offer it to the public in good time, through the medium of your esteemed publication.

Within a few days I hope to send you some specimen prints, unfortunately there is actually not one sheet of good albumenised paper in our town. Strange to say, the vilest trash found its way into this market, so that we are anxiously waiting for a fresh supply.—I have the honour to remain, dear sir, yours respectfully, Herman L. T. Haakman.

REGISTRATION OF SOUND.

Sir,—At p. 62, vol. ii., of the Photographic News is a description of a process, then imperfect, by which sound is made to register itself upon a surface prepared to receive it. M. Leon Scott was the happy man to develop, to some extent this happy idea, by himself conceived. It is also stated, at p. 70 of the same vol., that Professor Wheatstone, during a visit to Paris, was invited by the Abbé Moigno to inspect the papers on which these sounds had printed themselves, and is said to have been *greatly surprised and pleased* with what he *saw*. It is also stated that, as yet, no practical advantage has been gained by this discovery; but M. Scott is sanguine that, in course of time, he will so far improve his apparatus that it will be capable of printing a speech, which may be written off verbatim to the great saving of the labour of parliamentary reporters.

Now, sir, I have anxiously waited, and scanned the Photo News, for more than two years, for further information concerning this very interesting and promising discovery; but still no tidings. I feel the more interested in M. Scott's investigation from the fact that, about four years ago, I arose, after an almost sleepless night, with an irresistible conviction, arising out of the conception of the very same idea, that, in a few years our parliamentary reporters would be rendered useless. Some to whom I mentioned the notion laughed, and said, "Oh, you cannot lay hold of *sound*, there is nothing tangible about it—impossible!" Now we don't want to lay hold of it, but if we can devise a surface for it to run over, on which it must leave its visible footprints, we shall be quite contented. Others, not quite so backward at receiving a new idea, thought with me, that as the eye had already been imitated by photography, it was no very great matter to indulge the hope of the ear being represented at some future time by a discovery equally practicable. One gentleman to whom I named the probability of such a thing being matured, said, it was not at all unlikely, for he once heard of a man who was so wise that he could always tell what his neighbour was going to have to his dinner from the smoke of his chimney! Such is the lightness with which some, even intelligent folks, would treat this already partially developed idea; but may I ask you, sir, to impart the stimulus you are able to do, to the emulation of M. Scott by others, in order that this discovery, the results of which have been seen with surprise and delight by so eminent a man as Professor Wheatstone, may be utilized, and take its stand amid the wonders of this advancing age as a great and stubborn reality.—I am, sir, your obedient servant, Phonautography.

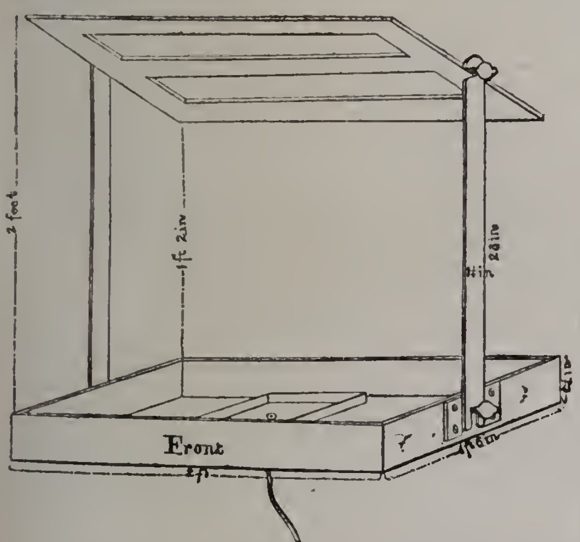
[We have not heard anything more of the subject since the publication of the facts at the period to which our correspondent refers. Possibly some other of our correspondents may have heard if any further progress has been made.—Ed.]

Apparatus.

Sir,—In a recent number of the News you request descriptions of dark tents, which have been found to work satisfactorily; and as I have made one which I have found to be thoroughly substantial and efficient, I send a sketch of the frame-work. The covering is formed of one thickness of black, and one of good yellow calico, sewn into shape, and then tacked on round the edge of the upper frame, and round the upper edge of the shallow tray which forms the table. In cutting out the calico I have done it so as to give the roof of the tent a very considerable inclination towards the back, thus allowing plenty of head room. The front of the top frame is two feet from the tray, the back fourteen inches. At the back there is a space, nine inches wide from the top to the bottom, without black calico, and here the light is admitted through two thicknesses of yellow calico. At the front the covering hangs down in the form of a bag open at the bottom to a little below the waist, round which it draws tight with a piece of whipcord running in small rings. When wanted for use I fix the tray upon the tripod, slacken the thumbscrews in the ends, slip the uprights into their places, where you will observe they are kept from swaying to either side by two small blocks, then tighten the screws against them. Next lift the top frame, slip the screws upon it into the notches at the top of the uprights, tighten the screws, and the tent is perfectly firm and ready for use. For carrying off the water I have a light wooden tray papered inside with porous paper, and then thoroughly coated inside and out with shellac varnish: the paper prevents the shellac chipping off. Four or five feet of india-rubber tubing carry the water to the ground and well out of the way. The cost without the tripod, but with fitting to attach the tripod to, was—

	s.	d.
Joiner	7	6
Calico, 5 yards of black, 7 yards of yellow	5	0
Four brass thumbscrews	1	6
Varnish, dress-maker, rings, tacks, &c. ...	3	8
	17	8

The weight is nine pounds.

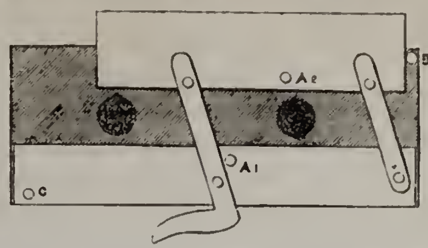


When not in use the tubing is drawn inside, the calico pushed into the tray, the top frame shut down upon it, the uprights laid upon that, and the whole held together with a leather strap with a handle at the side, forming a package $24 \times 18 \times 3$ inches.

As a practically useful tent I believe it will be found better than those sent out by some London makers at more than double the price; some that I have seen could be of no possible use except to sell. William Dodgson.

CAMERA SHUTTER.

Sir,—I have seen descriptions of many ingenious contrivances for opening and shutting lenses, but they seem to me, most of them, so complicated as to be unsuited for the amateur mechanic. In the hope of offering something more simple and adapted for home manufacture, I send you a diagram of one I have modelled for a stereo-camera. It consists, as I think you will understand from the diagram enclosed, of two plates, the under one having the diaphragms in it, the other rising and falling upon it, acting as a shutter, and worked by the lever and parallel bars, the under plate is at the bottom part, of double thickness, so that the shutter when closed lies upon the ledge, and the surface of the two plates is flush for the levers to work upon. A 1, A 2, are two studs over which an elastic band may be passed to ensure closing. B is another stud to which the band may be transferred from A 1, when it is required to keep the shutter raised for long exposure.



A quick exposure may be given by pulling the trigger, till the rise of the shutter is checked by the stud A 1, and releasing it.

If instantaneousness is required, put an elastic band, stronger than that over A A, over stud C, and the trigger, the latter being released by the finger, the shutter will be opened and closed quick enough for moving objects.

Differently sized stops may be furnished if required by circular rotating plates at the back; or, the simple shutter may be made in wood, all except the bars, by the amateur who has not facilities for working in metal.

You will perceive that by the action of this shutter, the foreground has more exposure than the sky, as the lower part is opened first and shut last, and further from the diagonal motion of the shutter the upper portion of the view is uncovered more slowly than the lower, which I consider a great advantage.

G. S. Penny.

Photographic Notes and Queries.

Clean Fingers.

About twelve months since, I noticed a letter from one of your correspondents in which iodo-cyanide of potassium was recommended for taking out stains of nitrate of silver, &c. This it does very quickly and thoroughly when newly made, but in time becomes nearly inert. Lately I have kept a saturated solution of cyanide, and another of iodine, in separate bottles, and when requiring to use the iodo-cyanide have formed it in the stain, by first moistening it with the cyanide then with the iodine. The result is the very rapid removal of silver stains from the hands or linen.

Those who wish to keep the silver entirely off their hands will find it easily effected by taking a pair of buckskin or other gloves made of soft porous leather, putting them on and giving them two or three thorough coats of india-rubber dissolved in coal naphtha, rubbing each coat well in, and allowing it to dry before the next is applied. When well coated they will form a pair of chemical proof gloves.—I remain respectfully,

William Dodgson.

Wigton, Cumberland, June 13, 1861.

Stereo Exchange Club.

Sir,—I have derived much pleasure from being a member of the above; and although some of the pictures I have received were not equal, I consider, to mine, I have been very glad to have them in exchange as the subjects are interesting, either from historical associations, or being localities which I had not visited.

What I now write to trouble you about is the following suggestion:—That in publishing a new list of names none but *amateurs* be admitted (which was one of the *original rules* of the club). I know of one *professional* whose name was in the last list, and there may be more.

With apologies for occupying so much of your valuable space, and many thanks for the trouble you have taken to make the Association work so well,—I remain, sir, your obedient servant,

An Amateur Member.

[We can scarcely see the object of our correspondent's suggestion, as we imagine that where professional photographers join in such an exchange, amateurs will, in many instances, be the gainers. However, we shall be glad to hear further opinions on the subject.—Ed.]

Talk in the Studio.

Scientific Fracas.—The hardest words which occur in photographic meetings do not lead to breaches of the peace; nor is it a common thing, indeed, for such circumstances to occur in any scientific assembly. The *Globe* states that at the close of a meeting of the Ethnological Society, on Tuesday evening, M. de Chaillu, of Gorilla celebrity, having taken offence at some remarks made by Mr. Malone, with whose name our readers are familiar, stepped up to him and held his fist in his face, demanding how he dared to speak of him as he had done, and finished by spitting in his face!

New Materials for Paper.—If the uncertain character of the materials used in the manufacture have hitherto been a source of embarrassment to photographers, it would appear that ere long troubles will be multiplied. A weekly contemporary remarks, that—"When it became evident that the paper duty was doomed, inventions were patented that had been in abeyance in consequence of the duty, and the yet more abominable annoyance to which manufacturers were subject. Within a few months many such patents have been either provisionally registered or sealed. Amongst others may be noticed one by Charles Stevens, of London, for an improved method of preparing sparte, alpha, the dwarf palm, and other gummy resinous plants, to be used in the manufacture of paper, being a communication from Eugene Helenus, of Paris. Michael Henry, of Fleet Street, has also obtained a communication from Paris, and patented an invention to facilitate the decolourising and bleaching vegetable substances, so as to obtain paper pulp. Damaged grain may thus be used to improve the quality of paper. The patent of Thomas Routledge has already passed the great seal for the manufacture of paper from an equal admixture of rags with Spanish grass and other fibrous plants. H. C. Jennings, chemist, London, has taken out a patent to convert tanner's bark and ligneous substances of various kinds into pulp, by means of a solution of lime-water and soda ashes. The organic matter when bleached is reduced to pulp by the machines now used by paper manufacturers. John Smith, of Birmingham, has also patented an invention to reduce sawdust, vegetable fibres, charcoal, and asphaltum into pulp or plastic material, to be moulded into toys and ornaments, and used in the manufacture of parasol handles, knobs for sticks, snuff boxes, pistol stocks, and for articles of greater strength, the composition will be moulded upon metal or wood. Letters patent are also granted to R. H. Collyer, of London, for an improved method of preparing paper pulp from straw, flax-waste, bamboo-cane, &c., capable of being moulded into ornaments, works and house decorations.

To Correspondents.

An Amateur.—You cannot do better than practise the collodio-albumen process as detailed in the article to which you refer. The preparation of the plates takes a little more time than some of the dry processes, but the results are more certain.

A Subscriber from No. 1 to No. 147.—We have heard good accounts of the objectives you name, but have not tried them. Personally, we should be inclined to prefer those of the house you named second. We cannot undertake the responsibility of selecting you a lens. Your developer turning milky when you add silver to it, would indicate that it was made of common water, containing carbonates, or chlorides, or both, instead of distilled water. Possibly it is decomposition to which you refer, and which more rapidly occurs from adding silver from your nitrate bath, instead of from a pure solution kept for the purpose.

J.—In a week or two.

X. P. R.—We have never tried the use of a silver bath rendered acid with nitric acid for the final exciting of collodio-albumen plates; but there are many reasons against the use of an inorganic acid under such circumstances. 2. The bath after sunning and the addition of a minute portion of acid ought to be ready for work. 3. The pungent smell of an old bath generally arises from the presence of acetic ether, which has gradually accumulated. Evaporation is the best method of getting rid of as much as possible; but it is very difficult to get rid of it entirely. Acetate of silver, in the bath, may be decomposed by adding nitric acid; but the acetic acid liberated remains, and is difficult, almost impossible, to eliminate. We shall be glad to receive your remarks on depth of focus in a form for publication.

G. G.—You have got the polish on a little unevenly. The operation necessarily requires a little practice to succeed perfectly. The hinges to which you refer, are made, and are used by camera makers, but by whom made or retailed we cannot tell you. Probably Mr. Meagher would let you have them, as we know he uses them; and also the screws you require. Of course professional camera makers can scarcely be supposed to be very anxious to help amateur mechanics, but we think it is possible you may succeed if you make application.

W. M.—We have not used the lenses to which you refer, nor can we at all undertake to endorse all that is said in descriptive advertisements which appear in our columns. From what we have heard, however, of these lenses, we have no doubt but that they are good for their price.

Caxton.—It is not a common occurrence for the image to disappear on the application of the fixing solution. It arises probably from an excess of organic matter in the image either from the collodion or nitrate bath, most probably the former. To remedy it try another collodion, or use the hypo much weaker. We remember on one occasion being seriously troubled with this tendency of the image to dissolve and then found that by using a slow developer, containing citric acid, the image which came up very slowly showed much less tendency to dissolve, even when all other circumstances remained the same.

C. Williams.—Positives on mica should not be backed with black varnish, as it degrades the tone to such an extent as to spoil them. Where it is available, we prefer a backing of velvet for positives on mica; but for your album we fear that this will be inadmissible. Perhaps the best plan you can adopt is to black varnish another sheet of mica, and place that at the back. By this means the tone will not be lowered as it would be by applying it to the back of the picture.

M. D.—1. We do not quite understand your description; but so far as we do, yes. 2. There is no method of diminishing the size of the image without either retiring further from it, or using a lens of shorter focus.

R. Keene.—We cannot tell where you can get a copy of the photograph you name. Do you not remember the name of the photographer? If you do, that would simplify the matter.

A. B. R.—Such a lens as you describe, made by the best makers, would cost from £5 to £12, depending upon the amount of rapidity you require. Send us your address and we can give you fuller particulars. The addition of nitrate of potash to an iron developer forms a small portion of protonitrate which improves the tone of a glass positive, but we prefer the method given in this column in our last in answer to John Picken. When your iron developer becomes peroxidized, it is better to throw it away. It is very difficult to work with a neutral bath in warm weather, but six or even four minims of acetic acid to each ounce of bath is a great excess. It is easier to work with a weak iron solution, say 10 grains to the ounce, when the weather is hot. A little free iodine in the collodion is a material aid to the production of clear pictures. We shall at all times be glad to hear from you, and any hints suggested in the practice of your own specialities will not be rendered unacceptable by little deficiencies in grammar or orthography, as it is a part of our duty to prepare such communications for publication. A man may be an excellent operator, and at the same time an indifferent grammarian.

Clericus.—Our own experience in the waxed-paper process has not been sufficiently extended to enable us to pronounce with certainty as to the cause of the defects in your negatives. We can, however, make some suggestions. We should, in the first place, decidedly express our conviction that they are under-exposed. The spots and freckles may arise from several causes. We glean from your letter that you do not saturate your silver bath with iodide of silver, this being the case, the iodide of silver, formed on the first contact of the iodized waxed paper with the silver is partially re-dissolved, and would give rise to the mottled effect exhibited. Insufficient time for the iodized paper to become thoroughly permeated by the silver solution, especially in a thick paper like this you are using, will sometimes have a similar effect. The defect may have been in the iodizing of the paper. If the iodide of potassium become at all decomposed, the iodine liberated, acting upon the starch in the paper, gives it a speckled appearance, which, by giving unequal sensitiveness, causes spots in the negative. To avoid the latter cause, the iodized paper should be dried in a dark room, as light aids the decomposition of the iodide of potassium.

Henry H.—The front lens of a half-plate portrait combination will generally cover about 9-in. by 7-in.

J. H. S.—Finger marks on the brass work of lenses may be simply washed off with soap and water, avoiding much soap. If it is much defaced, relacquering will be necessary. We cannot mention any maker's collodion upon which you can always rely as sufficiently textureless for micro-photographs. We have heard of a new portrait collodion, recently issued by Horne and Thornthwaite, which is described to us as giving an exceedingly fine and perfect film; but we have not seen it.

J. C. L.—The acetate of soda in crystals is meant, and the quantity stated is that recommended. You can try with less. We cannot recommend you a negative collodion; all those you name produce good results in some hands. Try a mixture of the last, and either of the others.

F. Brown.—The front lens of your Jamin lens will probably cover about 16 inches, if, as you state, its focus is about 25 inches. As a general rule, you may calculate on a view lens covering a square of about two-thirds of its focal length. The extra lens to be introduced between the front and back lenses, is to shorten the focus and increase the rapidity. Pine, or rather Christiana white deal, which is best for the purpose, will, we believe, answer perfectly well. Black varnish it well inside, and varnish it well with a bright varnish outside. We are afraid that portraits on pocket handkerchiefs would risk rapid destruction by washing powder, &c. Besides, to what a "base use" to put the portraits of one's friends!

Economy.—In order to obtain a more highly albumenized surface, take care to dry by artificial heat immediately after albumenizing. If the paper be hung to dry spontaneously, two causes immediately come into operation, which tend to reduce the amount of glaze on the surface: the albumen gradually soaks *into* the paper, instead of keeping *on* it; and if it be thin and limpid, a portion drains off the surface. Rapid drying prevents this. You will more easily get a high glaze on a stouter paper. The air-bubbles will only be got rid of by skilful manipulation; but the following method will aid you:—use a glass dish for the albumen, and let it rest on four feet at the corners, so that you can introduce a lighted candle underneath the dish, the light thus held will at once show you where any bubbles are, so that they may be removed. Or, you may lift the sheet and examine after it has been on the albumen a minute and then return it. This plan is troublesome. from the curling of the paper.

Z. O. You are a little in error in your calculation; 45 grains are one-fourth of 3 drachms, not 25. Otherwise you are right, and may safely use the formula

C. E. L. Acetate of soda, added to an iron developer, forms acetate of iron. It does not destroy the reducing power of the iron, but it makes the development much slower, and gives more density to the resulting negative It is, however, unstable, and loses reducing power by keeping. It is not necessary to use it, unless you desire its aid in obtaining intensity

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 149.—*July* 12, 1861.

PHOTO-LITHOGRAPHY AND PHOTO BLOCK-PRINTING.

In another page we publish a lengthy but interesting extract, from a voluminous specification just published of a patent, recently secured jointly by Mr. Francis Stewart Beatty, photographer and lithographer, and Mr. Thomas Alexander, M.D., of Dublin. The patent includes two distinct processes, one for photo-lithography, and one for producing, by the aid of photography, raised blocks for letter-press printing; but as they are both based on one principle, we presume they will not violate that condition of the patent laws, which makes it imperative that no more than one distinct invention shall be included in one patent. At the first glance, it struck us that nothing new was involved in this patent, as the production of the photographic image on the lithographic stone is by means of a transfer, as nearly as possible similar to that of Col. James; some alterations, and possibly improvements, in detail, being however proposed.

One of the chief and most interesting points, however, in this invention is, the attempt to gain, by a variety of means, the effect of half-tone or gradation of tints. The idea upon which this attempt is based is not new; but some of the means proposed we think are so. The mode of obtaining graduation of tones, which has before been suggested, is that of giving to the stone a grain or texture of some kind. Several modes of effecting this are here proposed. One method is to print upon the photographic transfer previous to placing it on the stone, a mezzotint, aquatint, or other ground by means of an engraved plate having such a ground. Another method is the use on the negative of a coating of resin in alcohol, which is described as having the "property, when drying, of dividing itself into innumerable small cracks, the intervening spaces being opaque or dark;" or, in other words, applying a spirit varnish, which is allowed to chill and granulate. Another method, which appears to have a similar end, is the mixing with the preparation of bichromate of potash, isinglass, &c., various "hard granular substances, such as fine emery-powder, peroxide of iron, glass, and flint finely ground in a mortar." How far these methods will answer the case proposed we cannot yet tell, as we have not seen any of the results; but the object is so desirable that we shall look with considerable interest for specimens. For reproduction of subjects in line or other objects which may be treated in black and white, the processes of Col. James and Mr. Osborne leave little to be desired; but as yet we have seen nothing that has, in any degree, grappled with the difficulties of half-tone; and until this is effected. the use of photo-lithography, except for reproductions, must necessarily be comparatively unimportant and limited.

Another novelty in the patent is the method of giving the image obtained upon the stone, by a direct process instead of transfer, permanent printing qualities. One of the chief disadvantages of the photo-lithographic processes in which the stone itself has been treated with the sensitive coating of organic matter and a chronic salt, has been the fact that the image rapidly chipped off, or wore away in the process of printing. It is proposed to remedy this by covering the stone with "liquid silex, silicate zopissa or aluminate of potash, or other liquid, having a hardening effect upon the stone." The sensitive coating is then removed, so as to bring the greasy ink into immediate contact with the surface of the stone, while the hardened surface resists the action of the printing roller; so that a much more durable printing surface is produced.

A method is also indicated by which an approach to coloured photographs can be obtained similar to the excellent imitations of water-colour drawings already in existence; the combination of the regularly-practised processes of chromo-lithography, and photo-lithography, being rendered possible.

The method of producing raised blocks for printing in conjunction with ordinary types of the common printing, if it can be carried out successfully, we regard as of the utmost importance. Our contributor, Mr. Hannaford, made some time ago some experiments in this direction of a very promising character, the nature of which was briefly indicated in our columns. Whether this method or these here indicated, which appear very simple and efficient in theory, will succeed when brought to a practical test, remains to be proved, and we shall watch with some anxiety for the results.

NEW RESEARCHES ON THE PERSISTENT ACTIVITY OF LIGHT.

BY M. NIEPCE DE SAINT VICTOR.

Upon exposing to a strong sunlight, during two or three hours, a newly broken fragment of a china plate, and then applying it to a piece of paper prepared with chloride of silver, after twenty-four hours' contact we obtain a reduction of the silver salt in the portion corresponding to that which has been exposed to the sun's rays, and none in that which has been protected from them. Certain *tender* porcelains acquire this *activity* more readily than others.

A steel plate, polished in one part, and made rough in another, by means of the action of strong nitric acid, and cleaned perfectly with alcohol, was solarized for three or four hours under the following conditions. Half of the polished and unpolished plate was placed under an opaque screen, the other half under a piece of transparent glass. The plate was then covered with albumenized paper prepared with chloride of silver. After twenty-four hours contact I obtained an impression of the unpolished portion which had been acted upon by light, but nothing from the polished part, nor from the unpolished portion placed under the opaque screen.

A strip of glass, strongly ground or roughened, and perfectly cleansed with distilled water, gave the same results as the steel plate.

I should observe that the light has less action under a violet-coloured glass than under a white glass.

These experiments demonstrate, therefore, that for the reduction of the salt of silver to take place, a chemical action is not necessary, as when we solarize a metallic salt with organic matter, or simply one of the two substances.

M. Arnaudon (chemist of Turin) has repeated some of my experiments in different gases, and the results are the same as those undertaken in the atmosphere. I propose to repeat them in a luminous vacuum.

In a tin tube, lined with card-board, impregnated with tartaric acid, and solarized to the point of very strongly reducing the nitrate of silver, I placed in the middle of the tube, without contact, a small bladder containing a weak solution of starch. After eight-and-forty hours, I ascertained that this starch feebly reduced Barreswil's liquid; other starch placed in the same circumstances, except solarization, produced no effect on Barreswil's liquid.

It is well known that all the resins become oxydized in the light and air, but yet I have not been able to solidify a varnish of bitumen of Judea with the *activity* acquired by a solarized body; a solarized bitumen no longer reduces the salts of silver; that, perhaps, is due to the persistent *activity*, as well as the light, not being able to penetrate and fix itself in the hardened layer of bitumen.

A plate of iron, oxydized in the shade, does not reduce the salts of silver; but it reduces them if it has been solarized.

It has frequently been announced that light magnetizes a bar of steel; but after removing every source of error, I have found it impossible to make a needle, solarized for a very long time under the rays of light concentrated by a strong lens, attract another sewing needle suspended by a hair, whether the light was white or coloured by being made to pass through a violet-coloured glass.

I have also enveloped a needle in paper impregnated with nitrate of uranium or with tartaric acid, and solarized; I have also suspended a needle horizontally in tubes containing solarized card-board, and the results were invariably of a negative character: which proves that the *activity* of which I have spoken above is not due to electricity, as some experimentalists have pretended.

I afterwards repeated the first experiments upon needles very feebly magnetized, to see if I could de-magnetize them; but the results were always negative.

From which I conclude—that this persistent *activity* given by light to all porous bodies, even the most inert, in all my experiments, cannot even be phosphorescence, for it does not continue so long, according to M. Edmond Becquerel's experiments: it is, therefore, most probably a radiation invisible to our eyes, as M. Leon Foucault supposes; a radiation which acts like a gas, since it does not pass through glass.

As to the magnetizing and de-magnetizing, I found it impossible to obtain any results with light alone.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Perspective.—The laws of perspective are so far useful to the photographer, as they test the accuracy of his production, and point out how he may represent his subject in order to obtain the best and most truthful effect. Aërial perspective has already been treated under various heads in these papers, so that we have now only to describe briefly linear perspective.

There are two kinds of linear perspective, of which it will be necessary to treat in this place, namely, "plane" and "panoramic."

In plane perspective the series of "visual rays" or lines, supposed to be drawn from the various points of the objects to be delineated to the eye of the spectator, are cut by a vertical plane, called the "plane of delineation," or the "plane of the picture." Thus, if in looking through a window we draw on the glass, previously prepared for such purpose, with strong gum-water, an outline of the objects seen, taking care not to change the position of the eye, such outline will be in correct plane perspective, and the glass will be the plane of delineation.

Some of the more important terms employed in linear perspective, will require to be shortly defined. These are:—

1. The point of view, or point of station.
2. The point of sight.
3. The horizontal line.
4. The vanishing points.

The *point of view* is, as the term itself implies, the position occupied by the eye of the spectator.

The *point of sight* is that spot directly opposite the spectator, to which his eye is supposed to be directed when he looks straight before him.

The *horizontal line* is drawn through the point of sight parallel to the horizon. It resembles the boundary line where the sea and sky seem to meet. All horizontal receding lines must incline towards it; those above the eye, downwards, and those below, upwards. Bearing this in mind, it will readily be seen—as I have before shown—that some judgment is necessary in deciding its height in the picture. As a general rule it may be stated that in a view taken at a low elevation, the horizontal line should be drawn, at from one-fourth to one-third the height of the picture; at ordinary elevations, about one-third, or, perhaps, a trifle higher, and, from a high point of view, up to one-half above which, excepting in "bird's-eye view," it ought never to be placed. From not knowing this rule photographers frequently mount their prints in a way that is quite an eye-sore to the artist; charmed with the definition and detail of the foreground, they fancy that because it is good they cannot give too much of it.

The *vanishing points* all lie in the horizontal line, and to them horizontal straight lines, not absolutely parallel to the plane of the picture, converge. The point of sight is the vanishing point for lines at right angles to the plane of delineation; whilst the vanishing points for lines at other angles is, where a line drawn from the point of view parallel to them, meets the plane of the picture. At these points, if indefinitely extended, the lines would appear to meet. Looking through a tunnel twenty-two feet square and a mile long, holding a piece of glass one foot from the eye, the opening at the further end of such tunnel will occupy a space on the glass, otherwise the plane of delineation, of only the four-hundredth part of a square inch, whilst at ten miles distant, or even less, the sides of the tunnel might practically be said to meet.

In *panoramic perspective* on a *plane* surface, the position of the plane is changed with each motion of the eye, and we thus obtain a panoramic view on a *plane* surface according to panoramic perspective, that is, with horizontals and perpendiculars vanishing in curves.

In "composition" photography, when figures are taken separately to be afterwards represented upon different planes of the picture, the proportionate diminishment of the said figures should also be carefully considered in reference to the laws of aëreal and linear perspective.

The following method will in this case serve your purpose. An object, say, six feet in height, and four yards from the perspective plane, is represented by two inches height in the picture. Now, supposing you desired to depict some other object sixty feet in height, and forty yards distant from the perspective plane, such object must in the picture be exactly the same height as the first; because by multiplying the dimensions given to the object in your picture by its distance, and by some actual object you wish to represent as above described, and then dividing the product of the photographed or drawn object by that of the real one with the distance, the *quotient* will give the size required.

Easy and important as it is to determine the relative sizes of objects as they retire from the eye, errors in this are by no means uncommon in the works of our "composition" photographers. For those, however, who are too idle for even this small amount of calculation, and who would rather produce their picture, and test it afterwards, a method will be found in calculating the height of the horizon as so many feet, four, five, or six, or more, as the case may be, and drawing a line from some object in the foreground of a certain height to give the relative height of other objects as they retreat, but this is a comparatively clumsy, uncertain method, and can scarcely be put in practice until after your picture is taken and printed.

Picturesque.—Natural scenes and objects possessing in themselves the elements of a picture would be thus described.

Reflected Lights.—Lights reflected from surrounding surfaces upon the shadowed sides of objects in their vicinity. Photography, owing to the inequality of chemical action in the shadowed and lighted portions of any image thrown upon the sensitized surface, derives no small aid from the presence of these reflected lights; tending as they do to reduce the more violent character of the contrasts of light and dark, and consequently equalize their photogenic powers. Actual shadows are never the opaque patches of dark still too commonly seen in photographs. In nature, delicate reflected lights steal into the depths of every shaded passage, but are so tender and soft that it is only in the hands of the most skilful and artistic of our best operators that they are secured in exposure, preserved in development, and not lost in the printing. To render the action of such lights more powerful, and so lessen the chance of losing them, many photographers use (in their glass rooms) screens for reflecting light, having either a white surface, or one of tin-foil; and so contrive to secure the proper amount of detail, and the true depth, transparency, and gradation of the shadows. When the brows of a model so project that the eyes are shrouded in the depths of their cavernous sockets, and would be hardly visible in the photograph, a swing looking-glass placed on the floor may be used to reflect a strong light upwards.

Repose.—That quietude of treatment and subject which gives little contrast without monotony, and a subtle gradation of tones without extending over a very large compass, constitute this quality of a picture as far as monochrome works are concerned.

Second Distance, or middle distance, both terms being in frequent use.

Scientific Gossip.

THE subject of the spectrum, and of spectrum analysis, is one which has, on several occasions, been brought before our readers in our scientific columns. We propose again reverting to the subject this week, in connection with a new instrument which has just been brought out by Spencer, Browning, and Co., of the Minories, from designs furnished by Mr. Crookes. It is called the spectroscope, and, for portability and efficiency, is certainly as perfect an instrument, of the kind, we have ever seen. When closed, it packs in a morocco case not more than $4\frac{3}{4}$ by $2\frac{3}{4}$ inches square, and $1\frac{1}{2}$ inches thick. When arranged ready for use, it forms a graceful-looking instrument in polished brass, consisting of two thin tubes about 4 inches long, diverging at an angle, in opposite directions, from a central chamber which contains the prisms. The front tube is furnished at the end furthest from the prisms, with an adjustable slit, and has at the other end a collimating lens which renders the rays of light, coming from the slit, parallel, before they pass through the prisms. The slit itself is furnished with a double movement; one, by means of a screw, altering its width, from $\frac{1}{10}$th of an inch to the $\frac{1}{1000}$th, or even less, until the knife edges close altogether; the other raising or lowering the entire slit, without affecting its width; so that with the highest magnifying powers the whole of the solar spectrum may be successively brought into the field of view. This seems to be a great improvement upon the old methods of effecting the same object by moving the telescope in azimuth as in Steinheil's instrument, or rotating the prism as in Bunsen and Kirchhoff's arrangement; the former making the instrument more complicated, whilst the movement of the prism the least fraction of a degree from its proper position of minimum deviation, throws the instrument out of adjustment. The other tube, on the opposite side of the prism chamber, forms a telescope which is fitted with eye-pieces of different powers. For ordinary work we prefer the lowest power, but for very refined investigations the highest powers are required.

The method of using this instrument is very simple. The two tubes merely require screwing into their places in the prism box, the slit adjusted to the proper width, and the telescope brought to the proper focus, when the observer may at once see the spectrum of any source of light to which the tube, carrying the slit, is pointed. Thus it is only necessary to place in front of the slit a spirit or gas lamp burning with a colourless flame, and then introduce into the outer envelope of the flame a fine platinum wire having on its extremity a portion of some soda compound, when the brilliant yellow line characteristic of this element, at once flashes across the field of view and remains there so long as the smallest particle of soda continues to be present on the wire.

In a similar way, we have been told by Mr. Crookes, that he has been able to perform with the greatest ease, and in a very few minutes, analyses of different iodizing compounds in general demand, finding sodium in one, potassium in another, cadmium in a third, a mixture of two or more iodides in a fourth, calcium, strontium, or barium in others, and so on. And all this with an accuracy which, by the old method of analysis, he could not approach without devoting some hours to the study.

We have likewise found this instrument of considerable value in testing water. A single drop of ordinary spring water, if evaporated on the end of the platinum wire and then introduced into the flame, will generally show the beautiful spectra due to potassium, calcium, and sodium, and thus affords a ready test of its value for photographic purposes. If one drop yields an appreciable quantity of lime to the spectrum test, the water should not be employed, as it is probably so hard that crystals of carbonate or sulphate of lime would be precipitated in the pores of the picture during washing. We also find it advantageous to test distilled water in this way. One sample recently sent to us having been found to produce spots and stains on our pictures, was tested in this instrument, when it was seen to contain a considerable quantity of soda and lime. The vendor had evidently sent out common in mistake for pure distilled water.

If the spectroscope is pointed to a yellow soda flame, and the slit reduced to very narrow limits, the soda line will appear *distinctly double*, if the high-power eye-piece be applied to the telescope. This is certainly a wonderful feat for so small an instrument to perform. Some years ago an instrument several yards long was required to see this line double; lately, the arrangements have been so far improved as to reduce this length to two or three feet; but it will surprise our scientific readers to hear that this optical feat can now be performed by an instrument only 9 inches long, capable of packing up into the size of a pocket-book, and weighing only 8 ounces.

When the spectroscope is pointed to the sun or a white cloud, the fixed lines in the solar spectrum are brilliantly distinct; and if the sun be allowed to shine through the slit, they can be seen from A in the extreme red, to beyond *l* in the lavender; D (the reversed soda line) being distinctly double.

If, whilst the spectroscope is pointed towards the sky, a piece of coloured glass is placed across the slit, the absorptive power of the glass is readily seen; and if it be yellow or orange glass which is under examination, the value of it for photographic purposes is apparent at a glance. A good piece of glass, one which will not allow photographically-acting light to pass through, will be seen to be absolutely opaque to the rays of light in the lavender, violet, indigo, blue, and half-way in to the green space: an inferior quality of glass will be found to be transparent to the whole of the green rays and some of the blue, and would thus admit of the passage of light capable of acting on bromide of silver, whilst it would not affect the corresponding iodide. The results which we have met with, whilst testing in this way differently coloured glasses for our own use, have proved so unexpected, as well as of such great value to ourselves and friends, that we are anxious to enable the readers of the PHOTOGRAPHIC NEWS to participate in these advantages. With this object, therefore, we have great pleasure in announcing that if any photographer will forward to our office one or more small pieces of coloured glass or other medium which he proposes to employ for illuminating the dark room, we will submit the same to examination in the spectroscope, and report upon the value of the different samples of glass, in a succeeding number of the PHOTOGRAPHIC NEWS. Amateurs as well as professional photographers will thus be placed in possession of all necessary information to enable them to have their rooms perfectly free from injurious light. The pieces of glass need not be more than an inch square, and should have a piece of paper gummed on one corner on which is written the name of the sender and any particulars which can be procured respecting the quality or composition of the glass, together with, if possible, the maker's name.

DEVELOPMENT AND STRENGTHENING NEGATIVES BY SULPHATE OF IRON.

BY M. A. GAUDIN.

Sulphate of iron has of late been largely substituted for pyrogallic acid in developing collodion pictures, on account of the great facilities it offers for strengthening the image. The pyrogallic solution is more certain, on account of the more definite condition of all the products employed. The silver bath is made with fused nitrate, which is neutral. Pyrogallic acid and glacial acetic acid are also very definite products, and in employing the latter in constant proportions, few variations are remarked; but the developing solution must be renewed every day.

With sulphate of iron the results are very variable, and we are frequently obliged to stop the developing without knowing why, if we wish, be it understood, to obtain the maximum sensibility, and obtain negatives fit for printing with at once.

The silver bath should generally be acid. It is frequently prepared with crystallized nitrate, but the proportion of acid the salt contains varies too much. It is better to prepare the bath with fused nitrate, and acidify it afterwards with a few drops of dilute nitric acid.

The sulphate of iron is of itself naturally more or less a reducing agent; but it is greatly too much so to act without the addition of an acid and an oxidation by contact with the atmosphere.

The formula which appears to me the best is composed of 50 grammes of sulphate of iron and 50 grammes of glacial acetic acid to one litre of water (or 5 per cent). The solution must have acquired an amber hue before it is used, which may be effected by shaking a bottle half filled with the solution, from time to time, and removing the cork for the admission of air. When the liquid becomes red, it is fit for use. It is poured upon the plate like pyrogallic acid in order to retain the nitrate of silver which is essential to the development of the image.

When the plate has had a lengthy exposure, it often happens that the picture is *fogged*, which does not appear to be due only to the concentration of the bath upon the plate; for in that case we should not prevent the veil by returning the plate to the bath before proceeding to develop it.

The salt of iron proper for development is always composed of a proto salt and a salt of the peroxide. The protosulphate of iron which, digested for some time with a tenth of its weight of nitric acid, and as much sulphuric acid, is red when diluted with water, and far from causing the picture to *appear* it *dissolves* it rapidly. By increasing the proportion of natural sulphate of iron, it becomes capable of making an image appear; but by prolonging its action, it makes it *disappear*, and it is only by increasing the proportion of protosalt that we arrive at a mixture which acts well, and exhibits a colour like that of beer, when diluted with water for use.

This sulphate will keep an indefinite length of time without deterioration. I have recently made use of some that has been kept in a well-corked bottle for twelve years, and found it to act very well.

The red sulphate of iron so rapidly dissolves the metallic silver which forms the collodion picture, that it may even be employed to remove the silver; by allowing plates to remain some time in a bath of this sulphate, they come out quite transparent, and collodion only will be found remaining on their surface.

Pictures developed with sulphate of iron are composed exclusively of metallic silver. This is why negatives are visibly strengthened when we pour over the glass plate—after washing with hyposulphite followed by a perfect rinsing—a solution of corrosive sublimate of the strength of 1 to 2 per cent., or a solution of chloride of gold of ½ or ¼ of one per cent.; after slightly acidulating them with hydrochloric acid. With the mercury they become blueish white, and with the gold solution they assume a golden hue.

M. Rivot passes the plate into a concentrated solution of sulphuretted hydrogen, after the application of the mercurial salt followed by rinsing, and, by repeating these operations a certain number of times, he often succeeds in converting a weak positive into an intense negative, in which the original image is perfectly preserved.

I was curious to learn if a negative, treated with the alcoholic tincture of iodine would become stronger by this change. I found the image well preserved by this treatment; the alcohol and iodine evaporating left a very pure yellow image, but too weak to print from.

The strengthening which to me appeared the best is that produced by chloride of gold; it yields very pure printed positives.

Without having recourse to gold, mercury, or sulphuretted hydrogen, it seemed to me advantageous to first strengthen the image by the sulphate of iron itself by placing the plate again in the silver bath after being well rinsed subsequently to the first development, and then pouring again some sulphate of iron over its surface; but there must be no tendency in the latter to fogging, and it must be kept carefully out of the influence of actinic light.

In conclusion, to employ sulphate of iron for the development of pictures; we must always have at command some *red* sulphate to add to the sulphate in use when the latter *fogs* the pictures; by this means we in no particular change the silver bath nor the supply of sulphate of iron, and we shall certainly prevent the appearance of the general fogging which is so easily produced.—*La Lumière.*

ON PHOTOGRAPHIC PRINTING.

BY COLEMAN SELLERS.*

The next best thing to originating improvements in an art is the careful selection from the discoveries of others, and the reduction to method of the gathered knowledge. Knowing nothing of the art of printing and toning but what I have learned from others (except in some of the detail), it may look like presumption for me to write on the subject; nor should I do so, did I not hope that my testimony might induce others to abandon the old toning and fixing bath for the more rational one of toning and fixing separately I am well aware that the majority of operators have adopted the improved processes for albumen prints, while they still adhere to the old bath for ammonio-nitrate prints, some because they fear to change, and others, having tried the new processes and failed or only partially succeeded, have not had patience enough to experiment; there are also some, I am sorry to say, who eschew all books, and who are quite guiltless of all extravagance in the book-buying line.

When the idea first occurred to me of introducing photography as an aid to the draughtsman in the machine shop, I did not think it would have grown to the extent it has, nor have been of such inestimable value. As the various machines were finished, and had been in succession transferred to glass with all the truthfulness of sun pictures, then with the increase of negatives came the necessity of producing enormous numbers of prints to meet the demand of our customers for pictures of our tools. This led to the employment of a boy, whose sole business was to print from as many negatives as he could manage at one time. With convenient arrangements for toning and washing, our con-

* Condensed from *Humphrey's Journal.*

sumption of paper has been sometimes as high as one ream a month. Some of these prints made two years ago seem as bright as when newly made; but others have begun to fade and had shown slight symptoms of fading before I changed our process. Since being convinced of the necessity of this change, I have tried every process that has been offered, and have got good results from a great many of them with albumen prints, of which we produce thousands; but with the ammonio-nitrate prints, I must say that for a long time I was discouraged, and many times was tempted to go back to the old bath, shut my eyes to the evils, and go it blind; but now I rejoice in having triumphed over the difficulties, and I see no trouble in the future.

In detailing my experience and publishing my processes I offer nothing new, but only show how I have profited by the teaching of others; and if these pages should meet the eyes of those who have originated the processes, and they shall recognise their own property, let them at the same time receive my hearty thanks.

It is a well-known fact, that to produce a good albumen print requires a more intense negative than an ammonio-nitrate print; and all writers agree in asserting that a good print cannot be produced from a feeble negative. In fact the contrast in the negative must be such as to enable the shadows to be quite bronzed without injuring the high lights; this bronzing cannot occur without considerable exposure. With ammonio-nitrate prints, toned in the old way, a feeble, or comparatively feeble, negative produces a good picture; but in all my experiments I have found that prints made from such negatives, toned in an alkaline solution of gold and afterwards fixed, are feeble and slaty, while prints from negatives designed for albumen paper have been quite readily toned. However, I have concluded that the process must begin with making the negative slightly more intense than is absolutely necessary for the old style of toning, and printing the picture deeper in the shadows. If, however, the negative is no more intense than is usual for plain prints, they had better be printed in diffused light, which, from the slowness of the operation, is not very profitable where many prints are required in a short time; hence, too much care cannot be taken in producing the negative of precisely the right degree of intensity.

In salting the paper there need be no change from what is usual. My plan is to use chloride of sodium in preference to chloride of ammonium, and to make the salting solution at the rate of 45 grains of salt to the quart of water. It is not well to salt more than enough for a week's work at one time, and keep it when salted in a dry place. Do not let the paper lay long in the salting solution, but merely pass it back and forth once as quickly as possible, then hang up to dry.

In preparing the ammonio-nitrate solution I prefer the plan recommended by Hardwich, which is this:—Dissolve 1½ oz. of nitrate of silver in 8 oz. of water; reserve from this 1 oz. of the solution; to the balance add, little by little, aqua ammonia until it has cleared; then pour in the reserved oz.; this should make the solution turbid again; shake well, and if it seems very turbid, add one drop of aqua ammonia, and shake well again: repeat this one drop at a time until it has begun to clear, but still so that it has quite a milky look. Next make up the whole bulk to 16 oz. with water.

In applying the solution to the paper I prefer to use a brush made by pinching some folds of Canton flannel between two plates of glass, allowing an edge of the folds to project about two and a-half inches wide, securing the whole by twine tied round the plates. The solution must be filtered before using, and what is poured from the paper should go into the stock solution, and not into the filtered lot from which the papers are being silvered. The plan we have adopted for silvering is, to place as many sheets as are designed to be silvered in a pile on a clean board used for the purpose, and tacking down the whole pile by the corners, then pouring the solution on to the top one, and spreading it over with the brush; the sheet can be torn loose from the tacks by inserting the finger under it, and then gathering up the corners so as to retain the extra liquid, it can then be poured into the funnel of the stock bottle. This tacking down the whole lot of paper at once saves much time.

The printing, as I have already remarked, should be deeper than what is usual for plain prints, that is, deeper in the shadows. According to my experience, the half-tones must be rather darker than what is wanted; but still the high lights must be left clear.

The print I enclose is one toned by the process I am about to describe, and by a boy who had had but one lesson. His prints have been uniformly as good since this was made, hence I infer that the process is reliable, and readily acquired. In relation to the toning solution I prepare three separate solutions. The first of which I label "gold solution," is the usual standard solution—32 oz. of water, 32 grains of chloride of gold; the second labelled "soda solution," is—32 oz. of water, 2 oz. of bicarbonate of soda; the third labelled "fixing solution for ammonio-nitrate solution" is —32 oz. of water, 6 oz. of hyposulphite of soda.

The prints collected at the end of the day's printing are washed in running water for about thirty minutes, being kept away from the light. While they are washing I prepare in a large flat dish the following solution:—water 32 oz., gold solution, 1 oz., if there are as many as six full sheets to be toned, *i.e.*, in the proportion of one-sixth of an ounce to each sheet of Saxe paper. Now fill a minim glass with the soda solution, and add this, a little at a time, to the gold solution in the dish until it has become neutral to test paper. Note the quantity of soda required to neutralize the 1 oz. of gold solution, and make a memorandum of it on the label of the gold solution bottle. This saves trouble; for, at another time, it is only necessary to add this quantity to each ounce of gold in the solution without repeating the test. But care should be taken to establish this quantity upon the mixture of every fresh sample of gold.

Into this neutral gold solution now lay the washed prints one at a time, until they are all, in face down. Begin at the bottom, drawing them out and turning the face up. Note if they have changed colour but are still of a reddish hue; do not let them become quite black; throw them into the water as they come to tone.

When they are all toned, pour your fixing solution into a dish and put in the prints. Now comes the important part. If the prints are over-toned, they will not redden in the hypo.; if they are under-toned, they will be very red; but if they are only slightly red, they will be right, drying of a dark rich colour, not blue and slaty. Five minutes is long enough for them to remain in the toning solution, and they must only remain in the fixing solution long enough to fix them. Wash well after fixing.

The above are the exact directions given by me to those I have taught, and who have in every case followed the plan with uniform good results. Desiring most earnestly that what I have written may be of use to some of my readers, and hoping that the knowing ones will pardon my dwelling on what I have no doubt is familiar to them, I leave the subject for the present—proposing, if our kind editor wishes, in another article to give an account of how to tone albumen prints alone, and ammonio-nitrate and albumen prints together, when both kinds are printed on the same day.

Let me, however, in conclusion, insist that, if any of my readers conclude to try the process I have described, they mix all the solutions fresh, and, on no account, use old ones.

(*To be continued.*)

HELIOGRAPHIC PRINTING.

This is the title given by Messrs. F. S. Beatty and S. Alexander of Dublin, to a process—or rather two processes—they have just patented. One is for photo-lithography, and the other for photo-block-printing. The details are given in the specification as follows :—

The object of this invention is improvements in the production of photographic proofs and their application to printing purposes. We have given to the processes, described in this specification the name of heliographic printing, and it is performed in the following manner :—We take a sheet of paper or any other substance free of granular texture, and we coat its surface evenly with tho transfer medium ordinarily used for transferring drawings, plaus, or delineations to stone or zinc, or we take any other suitablo transfer matter or composition used by lithographic artists, which answers the purpose; but we prefer the medium composed of two ounces of isinglass, quarter of an ounce of arrowroot, quarter of an ounce of gum tragacanth, and four ounces of flake, white, or washed chalk. The isinglass, arrowroot, and gum tragacanth are dissolved separately by boiling with water aud afterwards mixed together; the flake white or chalk is then added thereto, and coloured slightly with gamboge. This composition, when warm, is about the consistence of cream. We apply it in that state with a flat brush or sponge to the surface to be coated; the surface thus prepared, when dry, is hot-pressed or callendered.

Although wo have described paper as the surface on which lithographic artists spread their transfer medium and compositions, other substances free from granular texture are and may be employed. such as metal foils, vegetable parchment, and paper impregnated with india-rubber; these we beneficially employ in this invention to coat with the sensitive medium hereinafter described, or upon which to spread the transfer composition, and also for the transfer composition.

In addition to that we have already described we use gelatine, size, dextrine in solution, arrowroot, wheat, barley, and rice flours made into jelly paste, to which may be added flake white and gamboge, lucine or vegetable albumen, and also animal albumen, either alone or covered with the transfer medium. We sometimes impregnate the paper with a composition of asphaltum dissolved in turpentine, or benzolo and caoutchouc dissolved in chloroform.

If the photographic proof to be reproduced bo formed of delicate shading, we mix with the composition already described hard granular substances, such as fine emery powder, peroxide of iron, glass, and flint finely ground in a mortar in proportions according to the judgment of the operator.

In order to make the surface prepared as described capable of producing a photographic proof, we employ any chemical agent that possesses the property of being rendered insoluble in water by exposure to light and an absorbent of greasy matters when dry; we use, for example, bichromate of potash or other chromate salt having similiar properties. When in combination with isinglass, gelatine, dextrine, albumen, or gum arabic, and, although a saturated solution will answer, we prefer a concentrated solution of the bichromate of potash in warm distilled water, to which is added a solution of isinglass, gelatine, dextrine, or albumen (gum arabic giving inferior results), either separately or in combination with each other, the strength of the latter solutions being determined by the nature of the objects to bo produced. When cold, the combined solution will be of a deep orange colour, and is heated before using it. Further operations with it are conducted in a room from which daylight is partially excluded. A quantity of the solution as described is poured into an earthenware tray of the size to answer the prepared surface, and it is carefully taken by the corners and its middle allowed to come in contact with tho liquid, dropping the corners gradually to prevent air bubbles; if any be formed, they should be removed with a glass rod. Having allowed it to remain some minutes upon the solution, changing its position at intervals, it is lifted and allowed to drain, and primed up by one of the corners. When thoroughly dry it may be pressed or callendered if necessary; this operation of sensitizing the prepared surface may bo perfotmed a second time. By the well-known processes of photography, photographic proofs are obtained which may bo negatives or reversed negatives of tho objects which wo wish to make a printing surface on stono or zinc, and may bo photographic representations of natural scenery, portraits, drawings, engravings, written documents, manuscript plans, and printed matter. For convenience, we prefer the employment of glass negatives and reversed negatives in connection with a photographic copying frame. The negative or reversed negative being laid therein, the prepared surface is laid thereon, aud tho frame screwed down; it is then placed in the sunshine for a period of time, ten minutes or so. Diffused daylight will answer, of course allowing a much longer period according to the judgment of the operator. When sufficiently lighted, the copying frame should be removed into the dark room. Upon inspection it will be found that a faint image is formed on the prepared surface.

Tho next operation is to utilize this property of the chemical action of the light, and to change the nature of the imago in order to produce a printing surface. This wo perform by an impression taken from a metal plate executed by an engraver; it may have on its surface a mezzotint or aquatint ground, or it may be a ruled plate, the lines being horizontal and diagonal, of different degrees of fineness. Having determined on the grain to be given to the photographic proof, the plate is inked with transfer ink and wiped in the usual way to removo the extra ink, and an impression of it taken on the prepared surface containiug the photographic proof at a copper-plate or other press. When the impression is dry, or partially so, it is placed up in a zinc tray containing water, in which some gum arabic is dissolved, heat being applied uuder the tray. The proof is allowed to remain until the water becomes heated; it is then taken up and laid face down on water at a lower temperature, when it will be found that the printed impression will leave those portions of the proof unacted on by the light. A gentle rubbing with a pieco of Canton flaunel or a camel-hair brush will leave the photographic proof in printer's transfer ink, in consequence of its adhesion to the insoluble lighted portions, and will retain the grain of the plate from which it was printed.

Sometimes we print on tho sensitive prepared surface an impression of the granulated plate, and afterwards expose to the light with the photographic picturo laid thereon; this gives a reverse grain to the printed proof. Wo also take impressions from grained stones and zinc plates prepared with lithographic chalk; and in some cases we place on the photographic picture an aquatint ground made of spirits of wine and resin to produce an even shading. Subjects represented by lines may be treated with an impression from a very fine grained plate on simply applying the ink diluted with turpentine with a silk dauber or brush and clearing away the superfluous ink with a clean rag, leaving no trace except the colour, enough remaining to answer the purpose of transferring to stone or zinc. We print by the process described a number of impressions of the same photographic proof. If it be desired to produce a coloured picture, each of those proofs have printed on their surface only those portions which represent a colour, with its registering mark placed at the side or other convenient place, and this we perform by covering over with gum-water and lampblack those portions which we do not want to print; or we obscure it by any other method capable of being easily effaced without injury to the photographic picture. Those impressions, when transferred to a series of stone or zinc plates, and printed in successiou on the same copy, will produce a coloured impression of the photographic picture; or the same may be performed by the process at present in use by lithographic artists for transferring the subject of the photographic picturo entire on a series of stones or zinc plates, which have their surfaces previously prepared to resist the greasy impression, and then by colouring with transfer ink on each stone or zinc plate the portion intended to represent the colour, and printing from them in their respective colours on the sheet of paper which has the registering marks printed thereon.

For the production of printing plates or blocks for surface aud intaglio printing, we use a material capable of having a polished surface made thereon, glass on metals, for example. We coat this surface with the transfer medium and sensitive coating already described; the thickness of the transfer medium is much greater and stronger than that used for coating the prepared surfaces already described; the thickness of the coating will determine tho depth to be given to the finished printing surface Wheu tho coatiug is dry, it is exposed in the copying frame with a negative or reversed negativo placed thereon; and when exposed sufficiently to tho action of tho light, it is carefully washed in water at a low temperature, which is raised gradually, using a little weak nitric acid in the washing; by gently brushing with a camel-hair pencil a clean proof is obtained. When a dry cast is taken in plaster-of-paris, to which is added a quantity of washed chalk, the cast may be metalized in the usual way and electrotyped; but wo prefer to harden tho cast by immersion in liquid silex, silicate zopissa, or aluminate of potash, when it will be found that the cast so treated will bear the pressure of the printing press, and proofs may be taken therefrom.

We obtain printing surfaces from photographic proofs by floating upon the surface of a metal plate (zinc we prefer) the sensitive coating alone, and when dry expose it to the light with the photographic picture laid thereon in a copying frame as already described; and when sufficiently lighted we cover the whole plate with an acid-resisting composition known to engravers, consisting of printer's varnish and asphaltum, to which lampblack is added; this is laid on with a printer's roller or dauber. When the composition is dry, or partially so, it is laid in water slightly warmed, when it will be found that the prepared varnish will leave all the unlighted parts of the photographic proof in an acid-resisting varnish, acid being applied, or the galvanic principle used to assist the action of the acid by stopping out the fine parts with varnish, as the action proceeds the photographic proof will remain entire upon the surface, while all the parts acted on by the acid will be sufficiently lowered to leave the printing surface in relief by placing in the copying frame a reversed negative in place of the negative; a plate in intaglio will be the result in the after-process as described above. The photographic picture used for these processes we take in the camera, with the plain side of the glass towards the lens, in order that the finished printing surface and the copy be alike in position.

Again, after having obtained a photographic image by the means already described upon any hard substance capable of being polished and of bearing a great pressure without injury, such as a slab of glass, marble, lithographic stone, or iron, we cover the surface on which the image or proof is obtained with lithographic printer's transfer ink, and wash away the unlighted parts. We take an impression of the inked proof on lithographic artist's transfer paper, with or without any further rolling, and transfer the impression thus obtained upon stone or zinc for printing.

In the transferring by light a photograph proof upon a lithographic stone by covering it with the sensitive solutions, the proof or transfer being made thereon and covered with transfer ink and washed, the resulting printing surface will not be durable for printing any number of impressions in consequence of the sensitive coating being interposed between the stone and the transfer ink. We remedy this defect and increase the number of impressions that can be taken from a photographic or other transfer on stone in the following manner:—After having washed and cleaned the transfer in the usual way known to printers by getting rid of the gum, we heat the stone and cover the surface on which the photographic transfer has been made with liquid silex, silicate zopissa, or aluminate of potash, or other liquid having a hardening effect upon the stone. When dry, it will be found that the surface, except the portions on which the photographic or other transfer is, will be much harder and less liable to attract the greasy ink than before. The photographic transfer is then rubbed out, brought up by methods known to printers; this will take away the sensitive coating, and brings the greasy ink into immediate contact with the surface of the stone, while the hardened portions will resist the action of the printing roller, producing a more durable printing surface with less labour; and where no sensitive substance or composition interposes between the stone and the transfer of a photographic or other proof, we wash the stone free from gum used in printing by known methods, and heat its surface, and cover it with the hardening solution as described, thus giving better results than are now produced.

Having now fully described and set forth the nature and object of our said invention of improvements in the production of photographic proofs and their application to printing purposes, and the manner of carrying the same into effect, we wish it to be understood that we do not limit ourselves to the precise details or materials herein described, as the same may be varied without departing from the nature of our said invention, nor do we claim generally the use of bichromate of potash as a chemical agent for the production of photographic results, but what we do claim is,—

First, the use of lithographic artists' transfer mediums or compositions, or other suitable transfer matters or their equivalents to coat surfaces for the production of photographic proofs as described.

Secondly, the employment of metal foils and surfaces free from granular texture, and the coating of them with gelatinous, farinaceous, and albumenized combinations or compositions, and the covering of same with the transfer medium or otherwise as described.

Thirdly, the coating with bichromate of potash in combination with dextrine, gelatine, or albumen, the prepared surfaces as described.

Fourthly, the admixture of pulverized mineral and earthy substances in the transfer compositions as described.

Fifthly, the printing upon the photographic proof a tint in lithographic ink by an impression from an aquatint plate as described.

Sixthly, the printing of photographic proofs in colours as described.

Seventhly, and lastly, the method herein described of producing printing surfaces in relief or intaglio from photographic proofs, and especially we claim the application upon the surface on which the photographic proof is obtained of an acid-resisting varnish on being washed, the proof alone remaining, the other parts being without the varnish covering may be easily corroded away, thus leaving the proof in relief; reversing the negative produces a proof in intaglio. We also claim the covering with lithographic transfer ink (any surface having thereon a photographic proof) then washing away the unlighted parts, and when clean taking an impression of the same on transfer paper, and making a transfer of it on lithographic stone, and the hardening of the surface of lithographic stones on which a transfer is made for printing purposes substantially as described.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 10th July, 1861.

M. Niepce de Saint-Victor has communicated to the Academy of Sciences some further researches upon the persistent activity of light, the result of which tend to prove that this peculiar action, whatever it may be, is independent of chemical agency, and that light is without magnetic influence. M. Leon Foucault that the peculiar action of light observed by M. Niepce de Saint-Victor is an invisible radiation which behaves like a gas, inasmuch as it does not traverse glass plates. The idea of its being phosphorescence cannot be sustained.

About a year ago you published an account of some interesting experiments which had been made here upon a new mode of obtaining gas for illumination, which gave hope that the odious monopoly of the gas companies, with all the attendant nuisances of gas works, and street gas-pipes would be done away with. Results of such magnitude and importance could hardly be expected to be arrived at suddenly, for however sound in principle, the maturity of the working details must require time. Of the ultimate success of the plan referred to there cannot exist a doubt. Meanwhile, a new candidate has entered the lists of competition. M. L. Chandor lately exhibited his gas generator before a committee of the Society for the Encouragement of the Arts, consisting of MM. Combe, Péligot, Gaultier de Claubry, Barreswil, Alcan, Tresca, and others; presided over by M. Dumas. In their opinion M. Chandor's discovery is of the highest importance, as may be imagined, when it is shown that by merely turning a stop-cock, a torrent of gas is discharged, which may be conveyed to the remotest parts of a building, and which is a continual source of light, heat, and mechanical power at any point of its course. The apparatus, of very small dimensions, was installed at the foot of the great staircase leading to the hall in which the sittings of the society are held. The gas-generator, a metallic vessel of about 20 inches in length, breadth, and height, contains about eight gallons of a liquid that is easily vapourized; a mixture of equal parts of oil of naphtha, and spirits of turpentine, purified by sulphuric acid, and distilled amid a current of hydrogen gas, which, while impregnating; lowers the temperature of their boiling point considerably. A drum constructed with valve-wheels, similar to an ordinary gas-meter, is mounted on an horizontal axis in the interior of the generator. The level of the liquid, maintained by well-known methods, rises a little above the centre of the drum, which receives its motion by spring or weight like clock-work, the power of which must be proportioned to the distance the gas has to be conveyed. The number of revolutions required averages about 100 per hour. The vessel, or generator, is pierced with two holes furnished with stop-cocks, one of which gives admission to atmospheric air, the other givess issue to this same air transformed into illuminating gas by the hydro-carbon vapours with which it becomes charged. An indian-rubber tube of suitable diameter receives the gas upon its leaving a little reservoir of about 10 inches square, and conveys it to the pipes of distribution. In the present experiment the length of these pipes was about 200 feet, but practically there are no limits to which the gas may not be conveyed by the application of suitable pressure. The gas was burned at jets of various kinds, and the brilliancy and steadiness of the flame left nothing to be desired.

The result of this interesting experiment proves that without the necessity of laying down pipes in the streets, or huge gasometers liable to destructive explosions, we can, by adopting this simple apparatus, illuminate buildings of any dimensions, churches, theatres, manufactories, workshops, and ships or steamboats. Moreover, the gas has no offensive odour, and leaves no foul deposits in the gas-pipes, as may be imagined when it is known that this gas consists of 90 to 95 per cent. of atmospheric air, and of 5 to 10 per cent. of vapourized hydro-carbon. The great problem which M. Chandor has solved is that of transforming atmospheric air which costs nothing by the simple addition of 5 or 10 per cent. of vapour into an excellent illuminating gas, which may be produced and burned at any convenient spot. The economy both of plant and material, is remarkable; and the facilities it offers in respect to local establishments may be judged when it is known that at two o'clock on the day of the experiment no preparations at the hall had been made, at seven it was in full operation.

PHOTOGRAPHY IN GERMANY.

Elberfeld, 6th July, 1861.

I have tried the nitrate bath with iodine, recommended by Abbé Laborde (as reported by your Paris correspondent in No. 147), and find it very excellent. I dissolved 40 grains of pure neutral nitrate of silver in 1 oz. of water, added some iodide of silver in order to saturate the bath, and then added 2 grains of iodine. After 24 hours the first negative I made with this bath was a very excellent one, the shadows being quite clear, and the lights dense enough; if the bath remains some time in the same condition, and retains its sensitiveness, I think this modification may be well recommended. Collodion-positives, also by this bath, become very clear and of a remarkable fine tone.

I see English artists are not very content with the classification given to photography by the Commissioners for the International Exhibition; but Prussian photographers also are not more considered, by their Government, as artists, and have for a twelvemonth passed had to pay a tax for carrying on a trade. The small photographic establishments have to pay £1 4s., the larger ones £2 8s. a year.

Dr. Schnauss publishes, in the *Photographisches Archiv*, some experiments on the *harmonization* of photographic solutions.

The collodion process, he says, possesses, when compared with the other negative processes upon paper, albumen, &c., an extraordinary subtilty or delicacy of photo-chemical changes. To these alone the high sensitiveness and beautiful results of the collodion process are due; but, on the other side also, are its great difficulties. The centre of gravity of this whole process, especially if rapid fine negatives are to be produced, lies in the exact quantity of the *acidifying principle* in the three most important solutions:—1. The *iodized collodion*. 2. The *nitrate bath*. 3. The *iron developer*. Because this *acidifying principle* can be neutralized by opposed agents possessing *alkaline* properties, we also must contemplate this latter class of substances when harmonizing our solutions.

In chemistry the acids and alkalies are especially characterized by the fact that the first redden the blue litmus, or the Georginen paper; the latter ones make the red litmus paper blue, or the Georginen paper green. But in photography there are much finer differences, which cannot be examined by the before-named test papers. The photographic forces themselves must be used to find them out, *i. e.*, a proof must be made. By this experiment we find amongst the photographic chemicals, especially in those which serve to iodize the collodion, two classes of a strongly-expressed polarity, or of photographic oppositions, the knowledge of which contributes very much to a sure operation. In the negative, as well as in the positive collodion process, the *acidifying principle* must *predominate* in a more or less high grade, according to circumstances. In the negative process *acetic acid* must be added to the nitrate bath and developer, in the positive process *nitric acid* is added to the bath, and acetic (or nitric) acid to the developer. In order to bring a small quantity of the acidifying principle into the collodion none of the strong acids may be used; we must here take the substances which are *only by photography* known as acidifying, viz., the pure iodine, or an iodide containing free iodine.

In harmonizing the solutions especially their *age* is to be brought into consideration. All three solutions being freshly prepared no good results can be immediately obtained with them. The amount of acetic acid in the bath and developer is then to be augmented in order to obtain clear, vigorous negatives. We give, in the following, some indications as to the best preparation of the three solutions, always supposing that they must reach a certain age or maturity before they are able to show their whole worth.

The *collodion* should be composed of good fresh prepared pyroxyline, and a mixture of two parts of ether and one part of alcohol. It must be good and evenly flow over the plate, it should not form any streaks (or it is too thick), but must possess enough consistency to hold the iodide of silver which is formed in it during the immersion in the nitrate bath.

The iodizing solution consists of

Alcohol (·835 sp. grav.) ...	... 1 ounce
Iodide of ammonium ...	... 24 grains
Iodide cadmium	... 12 "
Bromide cadmium	... 6 "

This solution should stand some days and obtain a wine yellow colour before it is used.

One adds so much of it to the collodion that the film becomes dense enough.

For the preparation of a good and homogeneous film of iodide of silver with the *etherial* collodion the amount of water is also to be taken into consideration. I have made some experiments in this direction which I will communicate shortly. All were made with samples of collodion of the same composition, only differing in the amount of water. Every sample contained 60 parts of ether, 40 parts of alcohol, 1 part of pyroxyline, 1 iodide ammonium, ½ iodide of cadmium.

Experiment 1.—The collodion contained ether of 0·725 and alcohol of 0·800 spec. grav. It dried rapidly upon the plate, therefore the iodide of silver film became somewhat uneven, also the film repulsed the nitrate solution; but it possessed a good consistency, and could be easily transported or transferred. It did not show any trace of streaks.

Experiment 2.—Ether of 0·734, alcohol of 0·803 sp. grav. Colour dark yellow, dried also rapidly, and showed neither streaks nor traces.

Experiment 3.—Ether of 0·734, alcohol of 0·803 sp. grav. Colour rather clear, always rapidly drying upon the plate, and of firm consistency. The negative proof was excellent, and showed, after drying, no trace of streaks. The film was very even. I think the amount of water contained in this collodion to be the best; when it is augmented, the colour of the collodion is light yellow, the film becomes very even, but after drying small streaks and traces appear, or the film splits up.

M. Angerer, of Vienna, has shown at the Photographic Society some enlarged visiting card portraits obtained with Woodward's solar camera. We hear he has expressly made the voyage to London to see Mr. Claudet's arrangements for enlarging, and this gentleman has shown and told him, with his well-known amiableness, all he knew about the subject.

In the same session Herr Leman read a paper "On the Copying of Imperfect Negatives." A very thin negative should be copied upon super-extra albuminized paper and through green glass in the sun. Too much strengthened negatives are copied in the sun, without green glass.

Hard negatives, with too great contrasts, may be copied in the sun upon plain salted paper, or upon albumenized paper, prepared as follows:—One adds to the albumen as much zinc-white as it may hold without giving a precipitation. The more zinc-white one takes, the more sensitive becomes the paper, and the more rich become the proofs. The albumen is salted with chloride of ammonium, diluted with water and applied to the paper with the aid of a brush. The *alkaline* reaction in the paper may be the cause of the augmented sensitiveness. Paul E. Liesegang.

OPTICS AND PHOTOGRAPHY.

Sir,—Among the many subjects which photographers discuss there is one that is almost always evaded; I mean the optical part of the science. There is a great deal said about lenses of different kinds, but there is a deficiency of information of a simple character, so that a person could be made to *understand* something about his lens. I do not ask for fine and learned descriptions; in fact, I would rather not have that sort of information, for it would still further bewilder: but I should like some gentleman to take up this subject and give clear and understandable descriptions of what a lens really is, and in what consists its real goodness. I am sure I express the desires of many other photographers in manifesting a wish for this desirable information. It is the privilege of photography that everything connected with it is subject to free investigation. The chemical and the mechanical portions are pretty well understood, but there seems a disinclination to go into the optics. I know that a great deal has been written, and valuable papers contributed to different societies, but these all seem to take too much for granted, and assume that people know so much beforehand, and which, generally speaking, I don't think they do. I want to be put in possession of this useful knowledge to enable me to understand these valuable papers. At present they are sealed books to me; I read them through, and try to persuade myself that I understand them, but I know I don't; and I am sure there are many more, who would not like to acknowledge it, who are very like me. I have read nearly all that has been written on the subject. Mr. Hardwich has enough in his book to bewilder one, but not sufficient to enlighten. Scattered up and down in Mr. Sutton's "Photographic Dictionary" are short articles, but they are not clear enough; and he writes as if his readers understood all about mathematics. Mr. Price in his book has some very useful remarks about the use of lenses, and makes some interesting comparisons between the human eye and a lens; but the information I seek for he does not furnish. A short time since I did think that I was about to obtain my long-sought knowledge from Mr. Rothwell, in the *British Journal of Photography*. The first article opened well. I was willing to forgive the pompous air with which the information was to be communicated, so that it only came; but the subsequent articles were so trashy, and moreover, in some portions, so full of error—for little as I know I could see that he knew nothing, or worse than nothing, about what he was talking—that my hopes all fell; for it was plain as noon-day that there was no good to be got out of him. I was surprised that Mr. Shadbolt permitted his *Journal* to be the vehicle of such nonsense. I was pleased to see that he did not endorse it with his name, but I still cannot understand why he inserted the articles at all.

Although the information has not yet been supplied, I do not despair, for I think when the want is made known that some intelligent gentleman will supply it, though who that gentleman will be I do not know; Mr. Sutton, I think, is well qualified to do it, but he has committed himself to so many vagaries that one would hardly have confidence in following him. I do not know whether we may expect any information from the professional opticians. A chemist might hesitate before giving a formula, for one might make his own chemicals, but one could not make their own lens. Mr. Grubb has written some good things, but I did not like his papers on the optical centre; I thought them dreadfully difficult to understand. Anything in that style would never do. Then there is Mr. Ross; he must understand the subject well. His father could write well, and he has been born in the profession. Mr. Dallmeyer, whom many consider the rising optician of the day, could he not popularize his own subject? He read a learned paper once; some people seemed to think there was nothing in it, there was a precious sight more than I could understand. There is Mr. Shadbolt, too, he is well up in this subject, and has moreover, a happy method of explaining matters. I wonder whether he would undertake this desirable task. As to Mr. Rothwell, well I think he needs to go to school as much as any of us, and the information will be singularly useful to him. Dr. Antony has already gone into this subject, and perhaps he would be the coming man.

I know no subject upon which information would be so cordially welcomed as on this one of lenses. The humblest beginner, and the most accomplished artist have their lenses as their tools to work with, and they should understand more than they do about them.

There is the glass itself, this is understood to be something very different to ordinary glass; some lenses are of crown glass, and some of flint glass. Then there is heavy crown and light crown, or is it heavy flint and light flint? Why are there always *two* lenses put together to make *one* lens? Then in a portrait lens—this, by-the-by, has *four* lenses, yet is spoken of as if it were only *one*—the two front lenses are put as close as possible together, fastened in contact, while the two back lenses are not only not fastened together, but are of quite different curves, and have a piece of metal between them to prevent them coming in contact. There is all the mystery, too, of chromatic and spherical aberrations, of refraction and diffraction, of astigmatism and I don't know what else beside. Then there are single lenses, double lenses, triple lenses, and for what I know, quadruple lenses. Then concave lenses and convex lenses, and double concave and double convex lenses, and meniscus and aplanatic, and positive and negative lenses. I want made clear to me all about these as well as the orthographic and orthoscopic and caloscopic and panoramic lenses. What is the relation between the diameter of a lens and its focus, and what is the rule, or is there a rule how far the back lens in a portrait combination should be put behind the front lens? Where should the diaphragms be placed—before, behind, or in the middle of the lenses? What shape should the diaphragms be, round, square, or oblong? Should they be put horizontal, vertical, or oblique, and why? About the focus too, is it to have depth or not? There is the old standing contest of large *v.* small lenses, and shall we have *blue* lenses? Is the vexed question quite at rest, of the necessity of coincidence of chemical and optical focus? These are all matters which, like most persons, I understand more or less, but upon which I require more clear and definite notions, and where to look for, or how to obtain this information, I don't know; and, therefore, I frankly state my want and hope to call the attention of those able to supply it.

A Photo Student.

[It is quite clear that our correspondent has read sufficiently to be aware of the nature of his wants: and we cannot help suspecting that knowing so accurately the points requiring elucidation, he has more general information about the whole subject than he confesses to possessing. The truth is, however, that practical information on photographic optics in a popular form is a decided want. But the authorities on the subject are at variance on many of the most important points; and those best acquainted with the subject are least able to popularise it; thus many difficulties are in the way. We shall return to the question shortly.—ED.]

A PHOTOGRAPHER'S CONTRIBUTION TO THE VOLUNTEER MOVEMENT.

SIR,—Any of your readers who have visited the Cascata at Tivoli will remember how, sorely to their annoyance, they were followed by crowds of mendicants, destructive of any peaceful enjoyment of the picturesque; and how on arriving at two or three stepping stones across some insignificant gutter, their charitable emotions were appealed to by "Io ho fatto quel piccolo reparagione," or "quel *pontisin* è meo, Eccelenza,"* In photography it is somewhat similar; any minute bridges to cross small difficulties are not only weekly claimed by their designer, but the most insignificant bone of that class becomes "of contention" between two or three rivals hurrying for distinction. Acting on these premises it may not be altogether uninteresting to your readers to note the fact that a photographer put the Rifle Volunteer into the grey uniform.

Treasurer to the "Metropolitan Rifle Club," of some five or seven years back, the quality of light grey enabling its wearer in distance to "walk invisible" was, to me, as an Artist, well known: the first grey uniform was mine, and was engraved and published by Ackerman of Regent Street, the lay figure on which it was drawn being—your obedient servant, LAKE PRICE.

Dictionary of Photography.†

PYROXYLINE, *or* SOLUBLE COTTON.—This is one of the most important substances used in the present practice of photography. It is formed by the action of nitric acid on lignine, or cellulose. Either linen, cotton, or paper may be subjected to the action of the acid, but cotton is most commonly used. Cellulose submitted to the action of weak nitric acid is dissolved; but when the acid is sufficiently strong the character of the cellulose becomes changed; instead of burning on the application of fire it explodes, and becomes soluble in a mixture of ether and alcohol, or in acetic ether, &c. In order to secure the acid of sufficient strength and in a convenient manner, it is customary to add sulphuric acid to the nitric acid, which, by absorbing the water present, increases the strength of the nitric acid. The result is also produced at times by the addition of sulpuric acid to nitrate of potash, by which sulphate of potash is formed, and nitric acid liberated. Pyroxyline is what is known by chemists as a substitution compound, the action of the nitric acid being to remove a certain amount of hydrogen, and substitute equivalents of peroxide of nitrogen. Without entering further into the theory of pyroxyline we will proceed to some practical details of manufacture and characteristics.

The simplest method for the amateur of preparing a small quantity of soluble cotton is that which was most commonly practised in the early days of the collodion process, namely, by means of nitrate of potash and sulphuric acid. Various formulæ are given for the practice of this method; in that given by Mr. Hardwich the proportions stand as follows:—

Oil of vitriol	6 fluid ounces
Dried nitrate of potash ...	$3\frac{1}{2}$ ounces avoirdupois
Water	1 fluid ounce
Best cotton wool	60 grains.

* "I made that little repair," "that little bridge is mine, your Excellency."
† Continued from p. 211.

The nitrate of potash should be reduced to a powder and dried before weighing, to insure accuracy. It is then put a little at a time into a jar containing the sulphuric acid and water which have been previously mixed, stirring with a glass rod until all the nitre is dissolved. The temperature, which will have risen considerably at first, should be allowed to fall to about 150° Fah., and the cotton, having been previously pulled out into tufts, is put into the mixture, pressing each piece with the glass rod to the sides of the vessel to secure perfect immersion and the contact of the liquid with every fibre of the cotton. After remaining in the mixture for ten minutes, the cotton is removed and thoroughly washed in repeated changes of water until all traces of the acid and of sulphate of potash are removed.

We have referred to the temperature, and before going further it is important to state that a thermometer, the bulb of which can be inserted in the acids, is of imperative necessity, as the exact temperature plays an important part in the preparation of pyroxyline. Thermometers properly fitted for the purpose may be had for about seven or eight shillings each.

The method of preparing soluble cotton by means of mixed acids is most commonly adopted where large quantities are required, and is also often preferred where a more complete command over the relative strengths of acids is desired so as to produce at will pyroxyline with certain specified characteristics. Mr. Hadow, in a paper before the Photographic Society, was one of the first to systematize the results obtained by varying the strengths of the acids employed; and notwithstanding the attention which the subject has received of late years, his paper may still be read with profit. The following extract contains some useful hints for adoption where acids of uncertain strength are used:—

"In using the mixed acids, the limits are the nitric acid being too strong, in which case the product is insoluble, or too weak, when the cotton becomes immedately matted, or even dissolved if the mixture is warm. I have availed myself of these facts in order to produce collodion-wool by the use of acids, without the trouble of calculating the proper mixture according to their strength. Five parts by measure of sulphuric acid, and four of nitric acid of specific gravity not lower than 1·4, are mixed in an earthenware or thin glass vessel capable of standing heat; small portions of water are added gradually (by half drachms at a time, supposing two ounces to have been mixed), testing after each addition by the immersion of a small portion of cotton; the addition of water is continued until a *fresh* piece of cotton is found to contract and dissolve on immersing; when this takes place, add half the quantity of sulphuric acid previously used, and (if the temperature does not exceed 130°, in which case it must be allowed to cool to that point) immerse as much cotton, well pulled out, as can be easily and perfectly soaked; it is to be left in for 10 minutes, taking care the mixture does not become cold, and then transferred to cold water and thoroughly washed; this is a matter of much importance, and should be performed at first by changing the water many times, until it ceases to taste acid, and then treating it with boiling rain-water until the colour of blue litmus remains unchanged; the freedom from all trace of acid is ensured by adding a little ammonia *before* the last washing. Cotton thus prepared should dissolve perfectly and instantaneously in ether containing a little alcohol, without leaving a fibre behind, and the film it produces be of the greatest strength and transparency."

The amount of solubility in ether and alcohol, the characteristics of glutinosity or limpidity, coarse structure or its entire absence, sensitiveness, intensity, and permanency, are all regulated largely by the strength and proportion of the acids and the relation of their strength to the temperature at which they are employed. Within certain limits pyroxyline made with weak acids and at a high temperature tends to give the greatest intensity, fluidity, and structurelessness to the collodion, the film being short and powdery, as distinguished from that which is tough or horny; and is most suitable for negatives. A lower temperature and stronger acids give a pyroxyline collodion, from which it gives a tough transparent film most suitable for glass positives. A higher temperature with strong acids has an analagous effect to a low temperature with weak acids; whilst a medium in both respects tends to give the greatest solubility. As illustrative of the effect produced by the strength of the acids, we know nothing more interesting than the following experiment suggested by Mr. Sutton in his little work on the positive process.

"Procure some dry cotton wool chemically clean, some pure sulphuric acid, S. G. 1·84, some pure nitric acid, S. G. 1·5, and some rectified sulphuric ether, S. G. ·750.

"Use the fire-place of an outbuilding for the experiments. Put an old frying-pan, filled with sand upon the fire, and in this sand-bath place a pie-dish containing water heated to about 170° Fah. Then procure a breakfast cup and a couple of long thick glass rods.

"1st Experiment.—Put into the cup

5 drachms nitric acid, by measure.
5 drachms sulphuric acid ,,
25 grains cotton wool.

"Dense suffocating fumes rise from the mixture; these should escape up the chimney. Keep working the cotton wool about with the glass rods for 5 minutes, during which time the temperature of the mixture should be 150°. The temperature of the water in which the cup stands being about 170°, that of the mixture in the cup will be as nearly as possible 150°; but you must test it with a thermometer, the ball of which can be inserted in the mixture; for the preservation of an even temperature is of the utmost importance.

"At the end of five minutes, remove the cup, throw away the mixed acids, and put the cotton into a pail of water. Wash it quickly, opening it well, and rousing it about in the water. Then continue the washing in a basin, changing the water several times, and squeezing the cotton after each washing between your hands.

"When you have thoroughly washed and squeezed out all traces of the acids in this way, pull the cotton out into a large loose ball, and hang it up to dry gradually in a clean piece of netting. The cotton, when dry, looks pretty much as it did at first, but you feel a peculiar harshness about it.

"The first experiment yields pyroxyline of the most explosive kind. Be careful, therefore, of accidents.

"Repeat the experiment ten or twelve times, adding in the second experiment 30 minims of water to the acids, and increasing the quantity of water added by 30 minims in each fresh experiment. The twelfth experiment will, therefore, contain, in addition to the acids 330 minims, *i. e.*, 5½ drachms of water.

"We will now suppose the various samples of gun-cotton to be dry, and ready for an investigation of their proprieties.

"First—weigh them.

Sample 1	will weigh 43	grains
,, 2	,, 43	,,
,, 3	,, 43	,,
,, 4	,, 42	,,
,, 5	,, 37	,,
Samples 6, 7, 8	37	,,

"The cotton having increased in weight from 75 to 50 per cent., according to the quantity of water added.

"We now proceed to test the solubility of these twelve samples of gun-cotton in ether, S. G. ·750, and also to ascertain the various properties of the film, produced when the solution is poured upon a glass plate. Observe that ether, at ·750, contains a proportion of alcohol and water; the S. G. of absolute ether being only ·720.

"Weigh two grains of each sample of gun-cotton, and test their respective solubility in half-an-ounce of ether.

"Samples 1, 2, and 3 will be found to be insoluble. Sample 4 looks more gelatinous, and seems inclined to dissolve. Sample 5 dissolves completely on shaking the bottle. Samples 6, 7, 8, 9, 10 are soluble; 11 partly so; 12 not at all.

"Now compare the different samples of cotton. The first three or four are long and fibrous, the next three or four are somewhat shorter, the last three or four become very short, and break up into little short shreds, many of which are lost in the washing.

"The first three or four samples are called "Pyroxyline," and the last three or four "Xyloidine." But it will be seen that this nomenclature is imperfect, for it does not include the middle varieties, which are those with which we are concerned in Photography, viz., Nos 5, 6, 7, and 8. We will call them photographic gun-cotton.

"The first samples of pyroxyline are highly explosive. Place a small tuft upon the hearth, and apply to it the end of a red-hot piece of iron wire. It instantly goes off 'puff,' without smoke, and leaving no ash. The last varieties of xyloidine are merely combustible, and not explosive.

"Let us next examine the nature of the solutions made with samples between Nos. 5 and 10.

"Pour a few drops of No. 5 upon the finger, so that it may run round both ways. It dries quickly (producing a sensation of cold), and when dry, contracts strongly, looking like a piece of goldbeater's skin, stuck tightly round the finger. This is the hard contractile collodion. Its use should be avoided in photography.

"Now pour a few drops of No. 10 upon the finger. This also dries quickly, but when dry does not contract like the former, and instead of being transparent, is semi-opaque, or "opalescent," or "papyraceous," looking like a piece of tissue paper stuck round the finger. This is also a kind of collodion to be avoided in photography.

"The proper variety of gun-cotton for photographic purposes lies between these extremes.

"In order to try which is the best, pour a little of each solution upon a clean glass plate. But in order to make the experiment fairly, wait a day or two, until the floating particles in the collodion have settled to the bottom of the bottle; for you cannot properly filter collodion without a special apparatus.

"Examine the films before a strong light, with the help of a magnifier.

"Film No. 5 is not only hard and contractile, but shows structure, being covered with wavy marks, or lines.

"Films Nos. 6 and 7 are much better, and are nearly structureless; No. 6 is the best.

"Film No. 8 begins to get slightly opaque.

"In films Nos. 9 and 10 the opacity increases.

"No. 6 is, therefore, the best collodion, and on adding a little alcohol to it, the appearance of structure in the film altogether vanishes. It adheres tightly to the glass, without contracting, and cannot easily be washed off."

(To be continued.)

Newcastle Photographic Society.—The monthly meeting of the Newcastle-upon-Tyne and North of England Photographic Society was held at the Weaver's Tower, New Bridge Street, on Monday night, Mr. Dewar in the chair. The secretary intimated that owing to the illness of Mr. North, the paper which was expected to be read on the construction of glass houses, with special reference to the arrangement of light was not forthcoming. A general conversation took place relative to the merits of the different dry processes, Mr. Dewar recommending the "honey" process, Mr. Mc Kie the "tannin," whilst Mr. Laws preferred the wet collodion to any of the dry processes. Mr. Birnie exhibited an apparatus for the cleaning of plates, which is considered to be useful. The meeting was adjourned to the first Friday in October, when it is expected that the members will come forward with a great many specimens of their workmanship during the vacation.

Talk in the Studio.

Methylated Spirit.—In the Committee on the Inland Revenue Acts, on Friday last, the Chancellor of the Exchequer moved—"That there shall be charged, and paid for, upon every licence to be taken out by any person not being a distiller, or rectifier of spirits, or a dealer in, or retailer of, beer, spirits, wine, or sweets, authorising him to sell methylated spirit in any quantity not greater than one gallon at a time, the duty of £2 2s." The resolution was agreed to. The effect of this will be, we presume, that methylated spirits may be purchased retail, which hitherto has not been the case: and as for many purposes it answers as well, whilst the price is less than one-fourth of that of pure spirits; this may be regarded as a boon by photographers.

French Photographers and the Exhibition.—The French Photographers are disposed to resent warmly the proposed classification of photography. The Paris correspondent of a daily contemporary remarks: "The French commission for the Exhibition of 1862 has prepared forms of application for intending exhibitors, and has appointed seven places in Paris for their distribution. The chief office is in the Palais de l'Industrie. In connection with this subject, I may mention that the photographers here are exceedingly displeased with what they understand to be the decision of the English commission relative to the classification of their productions with the instruments by means of which they are produced. They say very pertinently that silks are not put with looms but with similar products, and therefore that photographs should be placed with engravings and lithographs. Some of the best photographers declare that they will not exhibit unless an alteration is made in the plan. Perhaps the matter only requires a little explanation, and I therefore merely report facts for the consideration of the commission."

Photography a Detective.—The various metropolitan police courts have recently been adorned by the aid of photography. We have before heard of the practice of photographing criminals when in custody with a view to a subsequent identification; but we have not seen such portraits forming part of the placards announcing a reward for the apprehension of persons "wanted." An absconding bankrupt, whose portrait, from the *degagée* deportment has manifestly been taken with far different intention, now smiles amiably, hat in hand, upon all who read the notification that one hundred pounds reward will be paid upon his apprehension.

The Comet.—Mr. Warren De La Rue, speaking of this unexpected and unrecognized astronomical visitor,—"I made an attempt on the 2nd to obtain a photograph of the comet in the focus of my reflector; but not the slightest impression was produced by an exposure of two minutes, although a fixed star was clearly depicted. Yesterday, the 3rd, I made several attempts to photograph the comet by means of Ross's No. 3 portrait lens mounted on the top of my telescope, and carried round by clock-work,—not the slightest trace of the comet was depicted in fifteen minutes, although the fixed stars were depicted. As Donati's Comet was photographed by similar means in seven seconds (not by myself), it follows that the present comet is considerably less actinic than Donati's." The *Athenæum* says—"We have seen other attempts made to photograph the comet, but without success. The contiguous stars left a strong impression on the prepared glass, but the comet itself left no trace of its presence."

To Correspondents.

R. G.—We presume that the markings to which you refer, are the irregular and indefinite cloudiness in the sky. It is somewhat difficult to come to a decided conclusion, from a print, as to the cause of somewhat indefinite markings in the negative, but we can suggest the probable causes. It sometimes happens that markings actually in the film, from some cause, such as a dirty plate, irregular development, &c., are not apparent before intensifying, but become very decided during that process. Another very common cause of stains, where intensifying after fixing and drying is adopted, is imperfect washing of the film before drying. Some slight trace of the fixing salt is left in the film, and when the solution of iodine, followed by pyro and silver is applied, irregular action becomes very apparent. In some cases, and with some collodions, when the intensifying is conducted after the plate is dry, irregular action arises from irregular absorption of moisture, where the stream from the tap falls heaviest, or where the developer is poured, absorbs, because of the mechanical force of the stream; and is repelled, or not readily absorbed, at those parts where the mechanical force is absent. Use one grain of iodide of potassium to one grain of iodine instead of two.

A Puzzled One.—The portrait of a gentleman is fogged from under-exposure and using a dirty plate. The stain on one side of the plate containing a portrait of a lady is also from a similar cause. There is, however, a tendency in your chemicals to the ready production of stains. A 40-grain bath requires to be decidedly acid, or there will be a tendency to stains. A new or colourless positive collodion frequently has a tendency to give stains, and may be remedied by the addition of a few drops of tincture of iodine. A little more acetic acid in your developer, and a little less iron when the weather is hot would be an improvement.

T. A. L.—The lens to which you refer is distinguished by admirable depth of focus. The utmost definition that ought, with due regard to ærial perspective, to be found in distant objects, is given by it. We have recently been trying it, and have two of the views before us now. Without any perceptible loss of crisp definition in the foreground, we have a well-defined but atmospheric middle and extreme distance. The results are highly satisfactory to all who have seen them.

Excelsior.—Lerebour's lenses are considered very good as French lenses; but they are not equal to those of the best English makers. The price mentioned, however, is quite out of the question. The price, as quoted in the lists of various London dealers for the quarter-plate size, is about £2 10s. The sum you mention, £4 10s., is more than the price of the half-plate lens. The stops which fit into the hood are intended for use in portraiture, when the light permits their use, and also for copying, &c. We should scarcely expect the compound lens to be suitable for landscape work; and we cannot tell you whether there is any arrangement for using the front lens for that purpose. If it be, as you describe, a quarter-plate lens, you will only be able to take pictures 4¼-in. by 3¼-in. The Jamin lens take larger pictures when the central lens, which shortens the focus, is removed. Sometimes portrait lenses may be used for landscape work, by the insertion of a central stop; and many portrait lenses are now made with an arrangement, whereby the front lens may be removed and used alone as a landscape lens. We cannot tell you where to get Lerebour's price list, except from Paris; but you will find his lenses quoted in the lists of various London dealers. The last two volumes of the Photographic News consist of the numbers issued during eight months; at present we see no reason to change that arrangement, in which case the present volume will be complete at the end of next month.

W. H. Fox.—The poisonous effects of cyanide of potassium are so rapid, that it is rarely possible to counteract them. Sulphate of iron, which is always at hand in the operating room, is the antidote which should be taken without a moment's loss of time; and if taken at once, the cyanide will be decomposed. Details will be found under the head "Scientific Gossip," in the Photographic News of May 3rd.

F. E. G.—We are sorry to have disappointed you in not attending to all your questions; but the simple truth is, that we cannot always with certainty make out your writing. In ordinary matters we can guess the meaning; but when we receive a statement of unusual occurrences or difficulties so we are puzzled; and after making our head ache, with the endeavour to decipher, or guess at the meaning, we lay the document aside for a more convenient season, which we are bound to confess does not always arrive. Will you be so good as to restate the points where you stumble, and we will once more try to help you. The stereo lenses you name are magnificent for stereo work; and they may be used for carte de visite; but they will not cover perfectly for a standing figure A proper lens is necessary for that purpose.

Dr. B. W. Switzer, Moradabad, East India.—Our German correspondent, Herr Liesegang, believes that the chemicals you used for the arrowroot paper were not pure enough. The best preparation for it is the "Real Brazilian Tapioca," potato flour cannot be used. The arrowroot solution as well as the nitrate should be somewhat acidified by citric acid. Then the paper remains quite white after the bath. We have often heard that pure chemicals and papers are very difficult to be obtained in India, as you state. We shall be very glad to receive the pictures you speak of.

A Photographic Printer.—Your difficulty most probably arises from the paper. Some samples of paper require toning much deeper than others, on account of the great loss in the toning bath. Excess of alkalinity in all or any of the solutions has a tendency to make the print turn a brick-dust colour in fixing. See that your silver bath is the full strength and a little acid. Let the toning bath be just neutral and tone sufficiently deep. The fixing bath should also be neutral, not alkaline. The gold toning bath with acetate of soda, as given in the Photographic News Almanac, has a tendency to prevent the defect of which you complain. Try it: we have had many excellent accounts of its value. The hypo, which you say is a fresh sample, may possibly be very alkaline; try it; and if so, discard it. If you wish to test its purity, weigh 20 grains of it accurately, and dissolve in half an-ounce of water; then take 10 grains of iodine, and powder. Add this to the hypo solution, shaking well. If the hypo be pure, the iodine will dissolve and disappear; if any of the iodine be left undissolved, the hypo is impure just in proportion to the amount of undissolved residue.

John Thorp.—In developing dry plates there is no necessity for alcohol in the developer. Alcohol is used in the developer for wet plates simply for this reason: the nitrate of silver solution on the surface has, in the course of exciting many plates, acquired a little alcohol and ether, and in order to make the developer flow easily, and combine at once with the solution on the plate, it should have just a similar quantity of alcohol. In dry plates there is only water on the plate, which should wet it thoroughly before applying the developer, which should only contain water, it will then combine with the water already there, and flow freely. Where it does not do so, it is want of a little more skill or care in the manipulation. Alcohol would only make the matter worse. We are glad to hear that the News is of so much value and interest to you. It is our aim that it should be so to all; and it is gratifying to know that we gain that end.

W. D. B.—There must necessarily be some trouble in applying a spirit varnish to a pane in a window, whilst in its place, on account of the difficulty of applying the requisite heat. There are two ways of getting over the difficulty. One is to heat the pane by holding a hot flat iron as near to it as you can do safely. The other, to take a piece of glass the size of the pane, and varnish it with the yellow varnish. Then fix that up with a brad or two against the pane already there.

C. E. L.—The circle of light in your stereographs is caused by the use of too small a stop. The No. 6 stop to which you refer is only intended for copying. The stop marked X is small enough for almost all practical purposes. The pictures always lack relief and boldness when a very small stop is used, and look flat and "adhesive." See recent articles on "Sharpness" and "Depth of Focus." Shading the lens with diffused light will also remove the circle of light.

Homo, Tannin, and some other correspondents next week.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 150.—*July* 19, 1861.

PHOTOGRAPHY AND THE EXHIBITION OF 1862.

The question between photographers and Her Majesty's Commissioners for the International Exhibition of 1862 still remains open. The *Journal of the Society*, published on the 15th, devotes a large space to the subject generally, and to the replies of the various societies, provincial and continental, with whom the secretary had communicated. We regret, however, that the official information does not seem in all cases to be brought up to the latest period. The Editor of the *Journal*, speaking, we presume, the sentiments of the Council, maintains that unless the concessions demanded by the Council be complied with, the Society must still decline in any way to co-operate with the Commissioners. Referring to similar views of the matter to those which we promulgated a few weeks ago, he remarks, "there are those who are for appointing a committee of persons who, by energetic and united action, and protest, might eventually accomplish what all seem to think desirable. But to this we have to say, that it would scarcely be dignified on the part of the Council, or courteous to the Commissioners, to undertake a position which is false and antagonistic at the commencement." Referring to the misfortune which it would be if photography were either imperfectly represented, or not represented at all, the *Journal* remarks, "the onus of this must fall upon those who force photographers to abstain, by a pertinacious persistence, in a classification which they themselves acknowledge to be wrong." We are not about to enter into discussion of the matter at the present moment, but we cannot let this pass without remarking that we were not aware that the Commissioners had anywhere acknowledged the classification to be wrong, and repeating what we before remarked, that in the case of such non-representation, or worse than that, inadequate representation, whilst the error will unquestionably be that of the Commissioners, the loss will be, at least to a very large extent, that of photographers and their art.

We shall now proceed to lay before our readers brief abstracts of the replies which have been received from the secretaries of the various societies to whom communications were made.

M. Laulerie, Secretary to the French Society, writes to state that the matter will be laid before the society, and, in the meantime, states that he has called upon the Commission, charged with the general organization of the French department of the Exhibition, who decidedly recognises the classification of Her Majesty's Commissioners as a philosophical blunder, and states its conviction that a special place will eventually be reserved for photography, under conditions the most suitable, and that in this place will be brought together the photographic works of different countries. This arrangement, it will be seen, is in accordance with that we have recently recommended. It is somewhat singular that as M. Laulerie writes under date the 18th of June, and states that he will lay the matter before the meeting on the 21st of June, which he did, we have no official account of their decision in the Society's *Journal*, published three weeks after that date.

Mr. A. F. Adam, Secretary to the Photographic Society of Scotland, states that the council of that society, whilst heartily concurring in the steps hitherto taken by the parent Society, "ventures to doubt if the course now proposed to be pursued," that is, the entire abstinence from contributing photographs. "is that best adapted to further the object which we all have in view, that of a proper representation of the art of photography." He adds:—

"It rather appears to us, notwithstanding the unsatisfactory nature of the Commissioner's replies, that further consideration of the subject is not absolutely foreclosed, and that the appointment of an influential committee from your Society might be one of the best, if not now the only, means of attaining our object."

Sir David Brewster, in his capacity of secretary of the Photographic Society of Scotland, writes to the Commissioners, maintaining the right of photography to a position amongst the fine arts. He concludes, somewhat inconsequentially, by remarking that "photography is yet in its infancy, requiring all the aid which chemical and optical science can afford it, and that any influential refusal to give it its due place among the fine arts must have an unfavourable influence upon its future progress." We fear that Her Majesty's Commissioners will scarcely regard the emphatic statement of its need of aid from science, as the strongest argument for admitting it to a place among the fine arts.

Mr. C. Heisch and Mr. J. Glaisher president and vice-president of the Blackheath Society, state that the council of that society entirely endorse all the acts and opinions on the subject published by the parent society.

Mr. A. H. Wall, secretary of the South London Society forwards a resolution, which we had the pleasure of moving at the last meeting, concurring in the steps already taken by the parent society, but suggesting that if it should be eventually deemed prudent, in lieu of any more satisfactory arrangement, to accept the separate department for apparatus and pictures offered by Her Majesty's Commissioners, that it be accepted under protest against cataloguing photography in any position which does not recognize it as a fine art.

Mr. J. Barnett, secretary of the North London Photographic Association, has communicated by letter on the subject, with the various officers of the society. The answers are classified as follows:—

"For placing photographs with the apparatus used in their production	1
"For placing photographs in a separate room in juxtaposition with that containing apparatus	2
"For placing photographs in the 'Fine Arts' department, and opposed to any compromise on the part of the Commissioners	6
"Indifferent	2
"No reply from	1
	12"

Mr. J. Cramb, secretary of the Glasgow Society, states that a special meeting having been called, the society "homologates" the hitherto published doings of the parent society, and has confidence in leaving the matter in their hands.

Mr. J. F. McKie, Secretary of the Newcastle Photographic Society, states that a special general meeting of that society entirely endorsed the published acts and intention of the London Society.

Mr. W. G. Thompson, Secretary of the Bradford Photographic Society, writing under date 13th June, states he will call a meeting of the society on June 17th, to consider the question, and will then report the result of their deliberations. No report of the result of the meeting is, however, published.

Mr. W. T. Mabley, Secretary of the Manchester Society, states that it was resolved at a recent meeting that the course pursued by the Society had the approval of the meeting, and that the members would join in remonstrating against the slight offered to their art.

The Birmingham Society are of opinion that the proposed classification is unfair, uncourteous, and unjust, and approving of all the London Society has done, agrees with it in urging upon all photographers the necessity of refraining from exhibiting or taking any part in the International Exhibition, until a more equitable position is assigned to photography as an art.

The Edinburgh Society having considered the subject at a recent meeting, empowered their Council to draw up a remonstrance against the classification.

Professor Playfair again writing on the subject, and considering the offer to give photography a separate department, after admitting the existence of certain difficulties on the subject, concludes by saying:—

"If the Commissioners were right in giving to photographers a separate class, then it can only be associated with Fine Arts on any principle of classification, although the difficulties will be felt of including in the section certain kinds of photographic pictures which cannot properly be considered to belong to Fine Arts."

Mr. T. D. Eaton, writing in reply to the communication forwarded to the Norwich Society, after stating that the Society is defunct, gives his personal opinion, containing some sensible remarks. He concludes by saying:—

"Before the Council take the strong step they seem to contemplate, it may be well to consider, whether their recommendation will exclude photographs entirely. If not, surely the art had better be fully represented (if not fairly), than partially and faultily."

We shall conclude our extracts from this correspondence, which largely represents public feeling on the subject, by the two following letters. The first is from M. Silvy.

"38, *Porchester Terrace, Bayswater, W.*
"*June* 4, 1861.

"DEAR SIR,—I have seen in the last number of the *Photographic Journal*, the difficulties arisen from the classification proposed for photography at the International Exhibition of 1862, and the claims put forth by the members of the Society to which I have the honour to belong.

"Notwithstanding the respect I feel for the opinion expressed by the honourable president, I must confess that mine is totally different, and that I have demanded from the Commissioners the favour of having my productions exhibited in the special mechanical department.

"However interested I may be in seeing photographic productions (to which I have been long devoted) highly estimated, still I cannot hide from myself that the chief merit is produced by the wonderful means that science has placed in our hands; and since I am in a country renowned for its horses, allow me a comparison which, I think, develops my idea:—

"Would the constructors of locomotives be right to enter their engines for the Derby in order to compete with thoroughbred horses?

"Such an idea has never been thought of, and I consider that the genius of photography will suffer no disparagement in being placed amongst the most wonderful machines which this era has yet produced.

"Should the members of the Society determine to send a collective note claiming another place than that indicated by the Commissioners, I regret much that, not having the same opinion, I shall feel obliged to withdraw myself from a Society of which, till now, I have had the honour to be a member.

"In begging you to lay my letter before the Committee, I remain, sir, yours, &c. C. SILVY."

Whether any other motive but a desire to be odd or bizarre can influence M. Silvy, who is himself eminently an artist-photographer, we leave others to determine. We conclude by the following letter from Mr. Lake Price, who is a still higher authority, as an artist and artist photographer.

"SIR,—It is no doubt supererogatory to attempt to add one word to the able arguments advanced in the admirable letter of the respected president of the Photographic Society of London, which indeed exhaust the subject. Still I may be allowed, as an artist and as a photographer, to express the extreme surprise I felt on seeing that in the programme for the International of 1862, the photographic lot was placed in the closest contact with 'Scarifiers!' and 'Clod Crushers!' hauled up along aside 'Ships' Tackle!' and estimated *pari passu* with the excellent cabinet work of the makers of our cameras. My own resolve was instant, not to accept the position. I maintain that in the hand of those whose artistic study enables them to know what they 'are going for,' the camera is as certain and legitimate a means of producing the desired result as the pencil itself, and that *the intention and thought of the individual is repeated in his works.*

"Now, apart from all questions of scientific study of optics and chemistry, of taste and knowledge of artistic requirement, it appears to me that the foregoing fact, clearly established as it has been in the works of many photographers, settles the question. If the producer can so mould the result to his will and to his preconceived design, can convey to the mind of another the *intention* of the picture, can make it satisfactory in composition and in *chiaroscuro*, it is decidedly NOT A MECHANICAL PRODUCT, and would, therefore, be clearly misplaced amongst its proposed fellows.

"I have no doubt, from the general feeling expressed, that, if the intended classification is insisted on, there is not one photographer, English or foreign, having the least pretension to be called an artist, who, by being found amongst the exhibitors in the section, will brand himself as a 'MECHANIC.'

"The entire absence of the most interesting results of one of the wonderful discoveries of our times will be a loss to all; but infinitely better thus than that it should be degraded by such unworthy association.—Yours, &c.,
"LAKE PRICE."

Notes and Jottings.

No. 8.

INTENSIFYING NEGATIVES WITH BICHLORIDE OF MERCURY AND IODIDE OF POTASSIUM.

AT page 293, Mr. Elliot gives the result of his experience in the strengthening of weak negatives by means of bichloride of mercury and iodide of potassium, and the process having now received a fair and full trial in our hands, we are desirous of adding our testimony to its excellence.

In photography, as in everything else, however closely persons may approximate in their general results, it will be found that in points of detail they differ more or less; and, therefore, it is very desirable that each should add his mite of experience to the common fund of knowledge. Commenting on Mr. Elliot's paper, we wish to drop in our small contribution.

The collodion should be of the strongly adhesive kind, bromo-iodized, and giving a moderately intense image on developing by iron alone. Should the collodion be over bromized it will be found that pyrogallic acid will be necessary in order to attain the proper intensity before applying the mercury and the iodide. A certain degree of intensity *must* be attained in the first instance, when the ordinary method of using these solutions is adopted; for, if the image be only brought out as a positive, the intensifying can only be carried to a limited point, and the negative will be weak and unsatisfactory.

By using the solutions *warm*, however, a great increase of energy is got, and many negatives taken in a weak light, and which would otherwise be useless, may be preserved. Even if cold it will be found that repeated alternate applications of the solutions, with copious washing between, will enable you to push the intensity further than by the method adopted by Mr. Elliot.

The plan we commonly adopt in manipulating is as follows:—As above stated, a moderate amount of intensity should be got in the first place. We prefer cyanide of potassium in fixing, after which the plate should be *well washed* and allowed to dry spontaneously. It is of the first importance that the film should be quite dry before proceeding further.

Our solutions for the second intensifying are:—

1.	Saturated solution of bichloride of mercury	1 fl. oz.
	Water	2 „
2.	Iodide of ammonium	4 grains
	Liquor ammonia	4 or 5 drops
	Water	1 ounce.

First wetting the film, the bichloride solution is poured on, and allowed to stand for about half a minute, and then returned to the measure. Washing the plate, the iodide is then poured on in its turn. By proceeding thus two or three times the proper degree of intensity is attained gradually, and we can stop it at the desired point.

The action of the bichloride should not be continued too long at a time, unless a *yellow* negative be desired. Generally, we may state that if the bichloride be applied last, the deposit will partake largely of the orange or yellow; if the iodide, prepared with the addition of a few drops of ammonia, as recommended above, the colour will be of an orange brown, enabling you to judge better its printing qualities.

Mr. Elliot recommends the application of varnish round the edges to keep the film on the glass. This ought not to be necessary; but we are aware that there is great difficulty in procuring collodion of sufficient tenacity. Nevertheless, the addition of four or five drops of water to each ounce, will often make a collodion very adhesive that would otherwise wash off. We prepare our pyroxyline at a moderately high temperature and weak acids especially for this purpose, and find no necessity for such a precaution as that recommended by Mr. Elliot.

We had purposed saying a few words on the application of this process to dry plate photography, but must leave that for a future "Jotting." Michael Hannaford.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

The Inorganic Acids.—It has been considered best to conclude the account of the different chlorides, bromides, iodides, &c., employed in photography, before noticing the corresponding hydrogen compounds of these metalloids. These compounds forming a well-marked group by themselves, and, consequently, admitting of more convenient study together, than if taken with the metallic salts. First in general importance, if not in actual photographic value, stands—

Hydrochloric Acid.—This acid is invariably made in commerce by the decomposition of sea salt by means of sulphuric acid; an operation which is one of the stages of the process for the manufacture of carbonate of soda. A mixture of one atom of common salt with one atom of oil of vitriol is heated in a horizontal cast-iron cylinder by means of a furnace; the anterior part of the cylinder is furnished with a tube through which the gaseous hydrochloric acid is conducted into a series of two-necked bottles half filled with cold water. The acid upon its evolution from the cylinder is allowed to traverse a long brick channel built slightly rising, through which a gentle stream of water is allowed to trickle down and meet the gas. Owing to the great avidity with which hydrochloric acid gas dissolves in water it is condensed by the stream and flows into proper recipients. Thus prepared, hydrochloric acid is very impure. On the small scale, or if required for photographic or chemical purposes it should be prepared in a slightly different way. A large glass flask should be connected by means of glass tubes and corks with three Woulfe's bottles (two-necked glass bottles) so that gas proceeding from the flask may bubble successively through each bottle. In the flask place 8 parts of common salt, and then pour upon it a cold mixture of 13 parts of oil of vitriol and 3 parts of water. The first bottle should have poured into it a very small quantity of water, the second bottle a quantity of distilled water, about equal in weight to the common salt employed, and the third bottle should contain a somewhat less quantity of water. The flask is then to be heated over a sand-bath until no more vapours are evolved, the temperature being gradually raised towards the end of the operation to nearly a red heat. The gaseous hydrochloric acid, with several impurities, will bubble through the bottles of water, which should be placed up to their necks in a vessel of cold water, and have moistened cloths on their necks to prevent a rise of temperature; the first bottle will collect the aqueous vapour evolved from the mixture, and will also serve to fix the less volatile impurities such as selenium, arsenic, tin, or iron. The water in the second bottle will be converted into about half as much again pure or nearly pure hydrochloric acid of a specific gravity, 1·145, whilst the third bottle will contain what little hydrochloric acid has escaped absorption in the second bath. This may be concentrated in a subsequent operation by placing it in the second bottle.

Pure hydrochloric acid, when perfectly free from water, is a colourless gas, which fumes strongly in moist air, has a peculiar, suffocating odour, and reddens litmus strongly. It is absorbed with violence by water with considerable rise of temperature. At the ordinary temperature water absorbs 480 times its volume, or nearly its own weight of the gas forming a solution of specific gravity 1·2109. The aqueous acid, when pure, is colourless, the crude acid, however, is generally of a yellow colour, owing to the presence of chlorine, iron, organic matter, &c. It fumes in the air, boils at a lower temperature than water, giving off the gaseous acid; the boiling point rising until a liquid is obtained containing 20 per cent of acid. It has a very pungent, acid odour, smelling like saffron when it contains iron.

The impurities of hydrochloric acid, especially the commercial unpurified variety, are numerous and important; even the so-called pure acid is liable to contain some of them; consequently, if the operator really desires to know if he has perfectly pure acid, it should be tested for each of the following contaminations:—sulphurous acid, sulphuric acid, chlorine, nitrous acid, arsenic, tin, or iron.

Sulphurous acid is produced by the sulphuric acid acting on the iron cylinders in which the crude acid is made. It is readily detected by adding to the aqueous acid a mixture of a little protochloride of tin, and twice its bulk of water. If sulphurous acid be present the liquid becomes turbid in a few minutes, appearing first yellow, then brown, and finally depositing brown sulphide of tin. *Sulphuric acid* is detected by diluting with four times its bulk of water, and adding a drop or two of solution of chloride of barium. If there is formed a white precipitate, or even milkiness in the solution, sulphuric acid is present. If the solution, filtered off from this precipitate, and boiled with a little nitric acid, gives a further white precipitate, it shows that sulphurous acid is present.

Chlorine.—This impurity is not at all an unfrequent contamination of hydrochloric acid. It is produced by the sulphuric acid containing nitric acid, or the common salt being contaminated with a nitrate. It may be detected by the yellow colour which it communicates to the liquid; by its peculiar odour; or by its bleaching properties. If a solution of sulphate of indigo be added to it, the blue colour will disappear. Chlorine likewise causes the precipitation of sulphur from hydrosulphuric acid when an aqueous solution of the latter gas is mixed with dilute hydrochloric acid containing this impurity.

Nitrous acid is best detected by mixing it with its own bulk of oil of vitrol, allowing the mixture to cool, and then cautiously pouring on to the surface of the liquid a strong solution of sulphate of iron, taking care that the liquids do not mix. A red colour is formed at the common surface of the two liquids, which may be caused to reappear after it has faded, by slight agitation.

Arsenic in the form of chloride is frequently, indeed, almost invariably, an impurity in hydrochloric acid. It is derived from the sulphuric acid. It may be detected in several ways. When the acid is diluted with water and mixed with sulphuretted hydrogen, yellow flakes of sulphide of arsenic are produced. When nitric acid is added, and the liquid evaporated to dryness, the metal is left behind in the form of arsenic acid. To purify the acid from arsenic, the best plan is to precipitate with sulphuretted hydrogen, and to filter the yellow sulphide of arsenic from the hydrochloric acid by passing it through asbestos; paper would not do, as it would be disintegrated by the strong acid. *Tin* may also be present in the form of chloride; it arises from binoxide of tin being present in the oil of vitriol. It is detected by the brown precipitate produced upon the addition of sulphuretted hydrogen; upon standing for some days the precipitate settles, and may be filtered off. It yields a globule of tin before the blowpipe. *Iron*, as well as *lime*, *soda*, and other fixed impurities may be readily detected by evaporating the acid to dryness at a gentle heat. No residue should be left if pure. If, however, there be a residue, its nature may be ascertained by dissolving in water, and adding appropriate tests. Thus, ammonia will precipitate iron in the form of a brown flocculent precipitate; the solution filtered from this will contain the lime which may be precipitated by oxalate of ammonia. The proper analysis of such a residue of this will, however, require the appliances of a good laboratory, and the knowledge of an experienced analytical chemist, and cannot, therefore, be attempted with any hope of success by one who has only a superficial knowledge of chemistry.

The Technology of Art as applied to Photography.

BY ALFRED H. WALL.

Sentiment.—To imitate with no other motive than imitation, and to imitate in order to express sentiment, will constitute no small difference. In the one case, the operator will make his selection, choose his exposure, and regulate his development with one idea, viz., that of securing the best possible imitation; in the other, selection, exposure, and development will all become subservient to some leading sentiment, the expression of which will constitute the picture. In either case entire truthfulness may exist, but while in the one production that truthfulness stands alone, in the other it blends intimately as it were with something more spiritually powerful, and not only expresses the simple forms of nature, but the soul of the artist. The picture is no longer dumb, but speaks with an eloquent tongue to every spectator; it has become endowed as it were with a mission, and spreads its influence among us far and wide, while the purely imitative production lives and dies in the first inspection, and however beautiful and rich in minor qualities, shows poor and mean by comparison with its mightier rival.

Shade and Shadows.—Surfaces which are not exposed to direct light are in shade but where projecting features shield certain parts from light more effectually, we term such shadows, or "cast shadows." The forms of cast shadows of course depend on the surface they are received upon, and the shape of the projection said, technically, to cast it. A scene will vary very surprisingly as the light falls at different angles, and the length and shape of the cast shadows become altered during the day. That which was devoid of any one quality of the picturesque at noon, becoming perhaps full of sentiment and beauty as the lengthening shadows and varied lights indicate the approach of evening. The effect of shade or shadow, therefore, should be duly studied when selecting a view, &c.

Simplicity.—Unartificial productions without exaggeration or affectation, which aspire only to the expression of the more familiar objects, scenes, and incidents of life, are said to possess this quality.

Studies.—Photographers have not perhaps been encouraged sufficiently, or no art could equal theirs, for producing studies of parts for pictures. I have already pointed out how valuable such from the nude must be, and in fact are, inasmuch as Rejlander and Robinson in common with myself and very many others, have executed such: moreover, photographic studies of heads, hands, and feet, of foliage, and foreground plants, of rocks, &c., have been frequently published, although, as a rule, operators do not give much attention to the production of such. In one of my papers from a common-place book, I pointed out how valuable even to the student of photography such studies would be, if regarded as an introduction to the practice of the art; and as those remarks more particularly applied to landscape, I may add that even in reference to portraiture, separate studies of heads, hands, and drapery would be no less important to progress in an artistic direction. The photographer would then learn what constituted perfect photography in reference to each of these as parts, and be the better able to consider the treatment they should receive in order to be well combined as a whole.

Subordination.—In Fairholt's dictionary of terms in art a very good illustration of the value of subordination is given. "Take as an example of gradation (subordination) the arrangement of rooms in a palace. We enter a simple vestibule, and pass thence to the ornamental ante-chamber: next we see the beautiful reception-rooms; and beyond these we find splendidly-decorated apartments. Without this gradation, no growing impression would be made upon our feelings."

Supple.—A pose which conveys an idea of flexibility instead of rigidity and stiffness.

Sweetness.—Mingled *clearness*, *simplicity*, and *harmony* are frequently indicated by this term, but I must confess I have no very clear idea of what it actually does mean, although I can pretty well understand the kind of picture it would be employed to describe.

Symmetry.—The fitness of parts in connection with the whole, or harmony of proportion.

Taste.—Displayed in practice by the harmonious perfection of various qualities when in combination and in theory, by the appreciation of the same. A cultivated and refined taste is about the finest thing you can possess, both as a source of pleasure to yourself and others, and, also, as an artist; I dare not add more or I should be tempted to fill a greater share of space than I have the right to claim.

Texture.—The truthful representation of the characteristics of different surfaces, the securing of which is one of photography's most striking beauties.

Tone.—A picture may possess great clearness of tone, or brilliancy of tone, or deficiency of tone, not only in reference to tones of colour, as warm, cold, &c., but also to those which pertain more especially to ærial perspective and chiaroscuro. Clearness of tone will result from the skilful juxtaposition and arrangement of tones, in securing gradation and breadth; brilliancy of tone will be the result of such judicious contrasts as may render the breadth more decided, and the chief passages more striking; and deficiency of tone will arise from the absence of sufficient contrast, want of gradation, or the destruction of atmospherical effect. Ruskin says,—"I understand two things by the word 'tone:'—first the exact relief and relations of objects against and to each other in substance and darkness, as they are nearer and more distant, and the perfect relation of the shades of all of them to the chief light of the picture, whether that be sky, water, or anything else. Secondly, the exact relation of the colours of the shadows to the colours of the lights, so that they may be at once felt to be merely different degrees of the same light; and the accurate relation among the illuminated parts themselves, with respect to the degree in which they are influenced by the colour of the light itself—whether warm or cold; so that the whole picture (or, where several tones are united, those parts of it which are under each) may be felt to be in one climate, under one light, and in one kind of atmosphere; this being chiefly dependent on that peculiar and inexplicable quality of each colour laid on, which makes the eye feel both what is the actual colour of the object represented, and that it is raised to its apparent pitch by illumination." In the same work, Ruskin, after pointing out how poorly white paper represents light, and how useless a mere black surface, reflecting a great deal of light, is to depict the "void spaces" of nature's deepest shadows, says.—"Here we are, then, with white paper for our brightest light, and visible illuminated surface for our deepest shadow, set to run the gauntlet against nature, with the sun for her light, and vacuity for her gloom." And he afterwards adds,—"It cannot but be evident at a glance, that if to any one of the steps from one distance to another we give the same quality of difference in pitch of shade that nature does, we must pay for this expenditure of our means, by totally missing half-a-dozen distances, not a whit less important or marked, and so sacrifice a multitude of truths to admit one."*

For this reason I have already pointed out how little of the two extremes of white or black we should aim at securing in our photographs. The soft and tender gradations of nature can only be imitated by watching, and expending with the reluctant and jealous care of a miser, our little stock of tones. The lavish waste of power displayed in the presence of too much black or too much white must result in that absence of tone and æreal truth which, being commonly seen, have created so much misconception in reference to photography as an imitative art. While the prodigal expenditure of white or black must prove destructive of tone, atmosphere, and breadth, a very little, judiciously obtained in your negative or positive, will throw the whole picture into luminous truth and natural relief, conveying the real beauty and sentiment of the scene to the mind of every spectator, although it is very possible that sundry sage critics we wot of would cry out against such a photograph as terribly wanting in the abrupt transition from extremes which, by some mysterious process of reasoning, they feel convinced give "*vigour, brilliancy*, and *roundness*," and in that hard cutting up into sections and patches which they misname "sharpness." (My good friend of the British will say, Here's "another half-brick from a Wall.") Your large black space is a piece cut out of the picture, an ugly, unsightly blot over the subtle gradations which make shadows look like shadows. Your patch of white swallows up in its unmeaning blank, the brilliant high lights, and all their soft and beautiful attendant tones; and thus, with the smallest means for the greatest ends, you lavish away the very paltry little stock of tones you possess with as much careless extravagance as if you could draw up and use darkness from the earth's deepest caverns, and bid the very sun himself shine out from your pictured landscape.

Nor must we overlook the importance of tone as associated with *expression*. (See *Chiaroscuro*, *Harmony*, and *Expression*.)

My purpose in writing the articles now concluded was duly expressed in their opening paragraphs; but during their progress, I have become more than ever convinced of the necessity for the information I have, through their agency, endeavoured to supply. These terms in the mouths of those who are profoundly ignorant of their actual importance and significance, could only be a mere meaningless jargon; but when certain critics in some of our Photographic Societies and journals took to advancing them in their arguments and criticisms with such meanings attached as were in *direct contradiction* to those which actually pertained to them, it was high time that somebody should endeavour to propagate enough knowledge to modify or prevent the mischievous tendency of so foolish a course; and, no one better fitted for the task being ready, or willing, to undertake it, I have done what I could.

Although arranged in dictionary form, I have, during my now completed task, only confined myself to simple definitions of meanings, when these sufficiently explained the technical phrase in question, and wherever information of a practically useful nature could be introduced, I have not hesitated to lengthen my explanations into the more important form of a short article.

Having an eye to what had been previously published in these columns, and thinking it would be unfair to regular subscribers were I to repeat in detail information already so ably given in the valuable papers contributed by Lake Price, some subjects have not been treated with the fulness their importance might otherwise demand.

To raise and improve the quality of photographs as artistic productions, and so raise to its just position our infant fine-art photography was and is, however, the chief end I had and have in view.

* See "Modern Painters," a work every photographer should be acquainted with.

TRANSPARENT POSITIVES.

By Professor Martin, of the College of Sainte-Barbe.

If the exposure in the camera has been too long for a positive, the operator must stop the development with pyrogallic acid at the moment when it may be feared that the shadows will become too thick and obscure the detail. In this case the reduced silver exhibits the peculiar red colour well known to experienced photographers who develop with pyrogallic acid. The action of chloride of gold does not cause this red colour to disappear entirely, and if it is not injurious to the positives employed in certain optical experiments, it is at least unsuitable for those intended to be transferred to paper.

Excessive exposure is not the only cause of the production of this red hue; the presence of an excess of acetic acid in the pyrogallic solution, or in the nitrate of silver, the employment of a collodion slightly alkaline, the taking of a picture a little too transparent or too harsh will also produce it.

It is not always easy to remedy these inconveniences. With respect to the exposure, it may be remarked that if it be insufficient, the picture will be incomplete in the lights, and will only give extreme lights and darks without half-tones. If the quantity of acetic acid be diminished, it is to be feared that the whites will not be sufficiently preserved.

In other circumstances, and by the employment of old collodion too rich in iodine and in ether, with baths containing too much free nitric acid, the reduced silver will take a grey tint; the image, imperfect in the shadows, is fogged, and even after the action of the chloride of gold, retains a blueish grey hue, both cold and disagreeable. In fine, the results are sometimes very excellent, but always very uncertain.

The object of the following method is to render the production of this kind of pictures more easy and certain.

The collodion I employ is a little richer in cotton and in iodide than the collodion described in my last communication (page 314) the nitrate of silver bath is the same.

The plate, sensitized in the usual manner, is exposed in the camera, a little less time than when the pyrogallic acid developer is employed, and the image is developed with sulphate of iron.

The silver reduced by these means is white, and gives only grey shadows. But this white silver must be transformed into black silver; which takes place when we pour upon the image, after being developed and well washed, *but not fixed*, a saturated, but non-acid solution of bi-chloride of mercury: the reduced silver becomes black by precipitation of metallic mercury. The picture is then carefully washed, and a solution of cyanide of silver in cyanide of potassium is poured over the plate.

This solution is obtained by dissolving 10 parts of cyanide of potassium in 100 parts of water, and pouring into the resulting liquid a solution of nitrate of silver of the strength of 10 per cent. until the precipitate of cyanide of silver, which is formed, ceases to be re-dissolved upon agitation; upon being filtered, the solution is ready for use.

We can replace the salt of silver by a salt of copper, which gives the same results; the metallic copper thus precipitated is black, and gives to the picture a tone exactly like that given by silver.

Hyposulphite of soda may also be substituted for cyanide of potassium, and the solution be prepared in the same manner, either with silver or with copper. Hyposulphite of soda, which has served for fixing negatives developed with pyrogallic acid, and whose action has become exhausted, gave very good results upon the addition of a salt of silver or of copper.

All these liquids will serve a great many times, those of silver especially, before their action will be exhausted.

When we pour one of these solutions upon the plate after the action of the mercury, we perceive the blacks to acquire great intensity; it is only necessary to wash the plate well, and fix with fresh hyposulphite of soda. Cyanide of potassium is not suitable in this case, however weak its solution may be; it whitens the reduced silver.

If it is intended that the picture be retained on the glass to be viewed by transparency, it is only necessary to leave it to dry, and varnish it if it be not sufficiently transparent.

When the picture is to be transferred, it must be very carefully washed after being fixed with hyposulphite, and immersed for a few minutes in water acidulated with sulphuric acid. The latter operation is necessary, as the collodion will have acquired an excessive adherence to the glass plate.

The same operations are applicable to cliches developed with sulphate of iron, and in which the blacks are sometimes found rather too grey.

PHOTOGRAPHY AT LITTLE PEDLINGTON.

Sir,—A famous work called "Little Pedlington, or the Sayings and Doings of the Pedlingtonians," once held up to the eyes of the world certain personages and events in order that from such representations others might take lessons, and improve.

Now we have photographers in Little Pedlington, and I do think their sayings and doings are as worthy of notice as those above referred to; nor do I think it improbable that by the means of a few letters I might do some little good to the London representatives of the art and science.

Doubtless you well know little Pedlington; for to whom is little Pedlington a stranger? Who is not familiar with that imposing town? Who, at least in imagination, has not entered its High Street, from the London road, and rambling on through its East Street, West Street, South Street, and North Street, and finding themselves in that fashionable promenade—the Market Square—have not gazed in wonder on its stately growth: have not admired that noble crescent with its twenty-four bow windows and its twenty-four green doors, ornamented with their twenty-four bright brass knockers? Who, we repeat, has not visited Little Pedlington?

Ah! how well do we remember when, from the picturesque heights of Snapshank Hill, whence one can, to use the words of its world-famed poet—

"Fondly gaze upon the scene sublime."*

we first marked—to return again to the mighty Jubb—

"Fields beyond fields, as far as eye can spy!
Above—that splendid canopy, the sky!
Around—fair nature in her green attire;
There—Pedlingtonia and its antique spire!"

How well can we recall the principal boarding-house in the Crescent, Yawkins's Library, in Market Square, and Snargate's in High Street. The Brewers' ex-out-house, now the theatre, and the fashionable skittle-ground, decorated with the brush of that mighty genius Our Daubson, whose one shilling profiles once won for him so vast a fame, and so glorious a name, wherever refinement and intellectual culture spread the love of art; and whose shilling photographs are now so anxiously sought by all who have a proper taste, and can appreciate the wondrous perfection of the scientific and artistic intellect in his magnificent productions!*

Think you, then, that while your new art and science has been originating journals and societies, and chemical discoveries, and optical inventions, &c., in London, Pedlington has been idly standing in the dark? No! ten thousand times no! and after that another and a louder no! again.

Is not the Rev. Jonathan Jubb, the bard of Pedlingtonia, president of the Pedlington Photographic Society? and is not Samuel Sirocle, member of no end of learned societies, president of the Pedlington Photographic Club? Does not Frank Staindigits, Esq. edit the *Photographic Purveyor*, and is not Yawkins editor of *The Pedlingtonian Photographers' only Journal?* Because your heads have been buried in the sand of your egotism, are ye to flourish your tails in triumph as the only birds in creation? No! for I, the Secretary of the Pedlington Photographic Society, will clutch the pen which shall point out how vital and how active is Little Pedlington's photography. Will show you how many of your boasted discoveries are due to Little Pedlingtonians; and how stale to the photographers of Pedlington are those improvements to which your journals and societies are devoted.

In my next letter I will call attention to the past doings of the Pedlingtonian photographers, after which I will, from time to time, send you brief reports of our societies' meetings, and those of the club, with occasional extracts from the pages of our journals.—I am, sir, yours most respectfully,

Tripod Cameron.

Hon. Sec. to the "Pedlington Photographic Society," and regular Contributor to the Photographical Purveyor.

West Street Lane, Little Pedlington, June 15th, 1861.

ON PHOTOGRAPHIC PRINTING.

BY COLEMAN SELLERS.†

In my last communication the subject treated upon was, the printing and toning of ammonio-nitrate paper. I now propose to say a few words about albumen prints. In regard to the paper employed, there is no doubt but that success or failure in the after processes depends very much upon the quality of the paper and its albuminous coating. But, as very few of us care about undertaking the preparation of it ourselves, we must so endeavour to simplify and render certain the various processes as to make up, in a measure, for the faults of the paper. All papers are not salted alike; hence, some require a stronger silver bath than others. As a general thing, however, a silver bath of 80 grains to the ounce is strong enough; and, if this fails with certain papers, I would rather not use them than increase the strength of the bath. In using the bath the silver hydrometer is an excellent instrument to approximate to the strength of the solution; but, as the bath gets old, due allowance should be made for the great quantity of nitrate of ammonium or nitrate of sodium in the solution. Hence it will not be amiss to read 85 for 80 grains in an old bath.

* "Pedlingtonia:" a descriptive poem by the Rev. J. Jubb.

* It is with painful feelings that we are obliged to state, that the national collection of paintings is still without that wondrous masterpiece of art, Daubson's Grenadier—which still—although with somewhat diminished brilliancy, may be seen at the further extremity of Yawkins's skittle-ground. Admission to see the painting may be had gratis, save on one day of the week, when the charge for admission is twopence.

† Condensed from *Humphrey's Journal.*

Much has been said about clearing a discoloured bath with kaolin, chloride of silver, and other articles. Some time since a most excellent article was published in this journal, recommending that citric acid should be added to the bath to clear it, by the formation of citrate of silver; this was siezed upon with avidity by many of my acquaintances, and with some—myself among the number—with success; but with others it was of no use at all. This led me to investigate the subject, and to arrive at the following conclusion :—Citric acid will form no precipitate in a solution of nitrate of silver; citrate of silver cannot be formed by the admixture of citric acid with a pure solution of nitrate of silver in water. But it is readily formed by the addition of any soluble citrate.

Hence, if to a saturated solution of citric acid we add a very little aqua ammonia, we will have an acid citrate of ammonium. A very few drops of this will cause a flocculent deposit, and will at once clear the bath of all colouring matter. This, however, must be used with great caution; for, by referring to any work on chemistry, it will be seen that citric acid has the peculiar property of assimilating with each of its atoms the three atoms of silver, while other acids only take up atom for atom. This can be readily tried by making, for instance, a solution of citrate of ammonium as above; also a similar solution of acetate of ammonium, adding each separately to portions of silver solution; the quantity of the deposit from the former will be surprisingly greater than from the latter.

Now, the reason why some succeeded and others failed in the use of citric acid is :—some of the baths were alkaline, while others were acid. Take any bath, neutralise it with soda or ammonia, so that it shall be slightly alkaline, drop into it a few drops of citric acid, and in an instant the whole mass will seem to curdle, and, as the deposit settles, the bath will be clear I like the action of the citric acid on the bath, and have made it a point always to keep my silver bath acid, while the toning solution is as nearly neutral as is possible. Hence I would recommend that, in mixing a fresh bath for albumen paper, it should be rendered acid with citric acid. In this condition it should be used until it begins to discolour, which it will do in time; then do not clear it with kaolin, but add to it a few drops of acid citrate of ammonia as above described: this will make a deposit of citrate of silver. Allow the bath to settle; pour off the clear liquid through a filter, but keep, as far as possible, the deposit of citrate of silver in the stock bottle, to which return the bath when not in use; filter any day before using, and the bath will never get discoloured again.

In silvering the albumenized paper I much prefer floating to immersion, and great economy can be practised in the way the paper is taken from the bath. If it be raised quickly it will be found that a large quantity of the solution is carried up with the paper, which runs off and is lost while drying. But if the sheet be raised quite slowly, the attraction of cohesion will arrest the gravitation of the fluid, and the sheet will be comparatively dry, so that little or no silver will drain off.

The toning solutions are the same as those recommended for the ammonio-nitrate prints, viz.: 30 grains of gold to 30 ounces of water, and a saturated solution of bicarbonate of soda; but the fixing solution should be stronger, *i.e.*, 10 ounces of hyposulphate of soda to 32 ounces of water; and the fixing bath for albumen prints should never be used for any other purpose. It contracts a very sickening odour from use, which I imagine might be prevented by the addition of a few drops of ammonia, though I have not tried it. Aqua ammonia has great keeping qualities, as is evinced in the albumen solution for Fothergill plates. Hence I have always added a little of it to the dextrine or gum I use for mounting, and to a solution of gum arabic which I keep for flowing over the finished negatives before drying.

But this is a digression, and we will return to the subject. I find albumen prints more difficult to wash previous to toning than the ammonio-nitrate prints, or it may be that they require more thorough washing. Too much care cannot be taken in removing all the free nitrate of silver from the surface, leaving only the chloride of silver and the albuminate of silver. The deposit of gold in the toning bath seems only to take place on the blackened chloride, and not on the white or high lights: hence, it is obviously wrong to use salt to destroy the free nitrate, because, by that means, we are coating the whole surface of the picture with white chloride and keeping off the gold from the blackened portions. I always wash for at least half an hour in running water, and then test some of the water with salt to see that the nitrate of silver is all gone.

The toning solution should be mixed in a very large flat dish in the following proportions :—32 ounces of water, 1 ounce of gold solution to each whole sheet of paper to be toned, that is, to every 17 stereoscopic pictures. The solution must be rendered exactly neutral by the addition of carbonate of soda in the manner and proportions as for the ammonio-nitrate prints. The prints will take much longer to tone than plain prints, and the toning must be pushed much further; they must be toned much deeper than they are required to be, to make up for the reddening effect of the hypo.

The dish, as I have said before, should be large—at least 14 by 18—so that the prints may be well exposed to the liquid, and they should not be continually moved about during toning, but at intervals during the process, as they tone much faster when at rest than when in motion. A good indication of their tone is, when they cease to look red by transmitted light. As they come to tone, throw into water, then fix in the hypo solution. When ammonio-nitrate and albumen prints are made on the same day, always tone the albumen priuts first; and, while they are toning and fixing, wash the plain prints, and then proceed to tone them in the exhausted toning solution for the albumen prints, and it is better, in most cases, to add, at least, 16 ounces of water to weaken it, the plain prints requiring so much less gold. Always fix the plain prints in a fixing solution prepared for them, and not in that used for the albumen prints.

By rigid adherence to the above directions I am sure good work can always be produced. Hoping that it may be of use to some of my readers, I leave the subject of photographic printing. In my next I propose to give an account of some experiments in collodion making, sensitizing, and using, which may prove useful to those who wish to make their own collodion.

CARTE DE VISITE PORTRAITS.

The *Saturday Review*, in a recent article on this subject, accords to first-class photographic portraits as high a position as the most enthusiastic photographers claim for it. As all outside recognition of the art claims of photography, are important and interesting at the present moment, we present our readers with the following telling extracts :—

"The last fashion of *cartes de visite*, as they are still called, combines many attractions for popularity. If the curious purpose which originated their trivial name was ever seriously intended, it never took effect. Happily, people pay morning calls with a less expensive visiting-card than that which the photographer furnishes. And though, as we have been assured, on one occasion a letter simply inscribed with an anonymous photographic portrait and the address of the post-town reached its destination through the post-office, yet a less public and practical use of our bodily presentiment is alone likely to survive. No drawing-room table of the day can be considered furnished without its 'photographic album;' and among the pretty toys of the season few can proffer so many substantial merits. Our domestic and political associations, our tastes and prejudices, our party or our piety, find ample scope within the catholic range of the favourite morocco volume which suits a necessity and a characteristic of human nature. It is at once a mild form of hero-worship and an illustrated book of genealogy. It does duty for a living hagiology, and it will supersede the first leaf of the Family Bible. If we happen to be as liberal or as lax in our symphathies as was Alexander Severus, our *lararium* may contain, besides the effigies of our own Royal Family—which in the real British album do duty as grace before meat—Cardinal Wiseman and Dr. Cumming on opposite pages, Cavour *vis-à-vis* with the Thalestris of Naples, and a popular preacher in dangerous proximity to a Pet of the Ballet. There is one practical use of a selection of *cartes de visite* which ought to be attended to—it helps visitors wonderfully as a key to the tastes or prejudices of the house. Especially in the embarrassing half-hour before dinner it is as well to be possessed of the party adopted by the Amphitryon. Here a photograph of the Bishop of Oxford—or perhaps of Cobden and Bright—may act as beacons to the incautious sailor in the narrow seas of small talk; while, in the way of suggestion and hints for that same dreary time of blankness of mind alike and stomach, there is nothing better than to fall back upon the pictorial Grove of Blarney on the table, which is sure to offer some opportunity of showing one's knowledge or one's ignorance of things in general or of men of the time. If there is not a Buckstone there may be a Bellew in the long series of contemporaneous biography; and when the ballet and the pulpit, the senate and the prize-ring, *haut-monde* and the *demi-monde* are alike laid under contribution for portraits—when we are admitted with equal familiarity into the Premier's cabinet and the *prima donna's* dressing-room—even the dullest mind in the dullest half-hour of the day may find something to talk about. Not but that a series of the *cartes de visite* has higher recommendations. It is something that a gallery of contemporaneous portraits of unimpeachable fidelity may be purchased for as many shillings as guineas used to be expended on Houbraken's heads or on Lodge; and it is a higher feeling than any prompted by the caprice of fashion, or by a vulgar curiosity which interests us all in the living form and features of men of renown."

Referring especially to the first of a gallery of photographic celebrities just issuing by Mayall, the article proceeds:—

"A series of living statesmen has been commenced, and the private chapel of political hero-worshippers has the chance of exhibiting an iconostasis of living worthies, collected on principles of an advanced eclecticism. Lord Derby leads the van, and the admirable photograph of the great Conservative leader, just published, is as remarkable a work of art as the process has ever produced. Somehow or other, apart from the mere mechanical perfection with which the accessories and texture of modern dress are rendered in this charming picture, there is an ideality in the portrait which has hitherto been scarcely attained."

We should like to call the especial attention of those who deny to photography the position of a fine art, to the following remarks:—

"It is the highest praise of photography if it can ever compete wish a first-rate portrait, and Grant's fine full-length of Lord Derby does not more satisfactorily bring out the mind and character of its subject than does Mayall's superb photograph. There is life and vigour in every lineament; and if we could have had this sort of likeness of the Cecils and Walpoles, the Pitts and Burkes of old time, we should have known perhaps something more of English history. If, as is unquestionable, one half of our conception of Charles I. is gained from Vandyke, posterity, if photographs are destined to reach posterity, will know more about Lord Derby and Lord Lyndhurst from the manipulating skill of Mr. Mayall."

GROUPING AND ARTISTIC EXPRESSION.—THE GROUPING OF TWO OR MORE PERSONS.*

BY L. M. DORNBACH, S.B.

HERE the same general rules which were given for the position of a single person must be observed, but to those several more will be added, having special application to the particular case under consideration. One of the principal things to be followed is, to aim at giving life and natural ease to the picture as well as the correct arrangement of the individual parts.

The photographer must always bear in mind that both objects and their corresponding images, when in focus with a portrait combination, are the segments of spheres, and hence all the members of a group must be at the same distance from the instrument, that is, not quite in a right line, but in the arc of a circle whose centre is in the axis of the lens.

If only two persons are to be grouped, the same observations that were made with regards to one are nearly all that need be observed, only it is well to pay particular attention to the direction of the eyes. The direction of the eyes should never cross each other between the persons and the instrument; the best way is to allow both persons to look at the same object on or near the instrument, or at two objects at about the same distance from each other as the persons, thus making the direction of the eyes nearly parallel; above all things, we must guard against the two persons casting their eyes apart; but this is only a particular case of the rule that the direction of the eyes should not intersect in front of the instrument, which would be the case in this instance, as they would cross each other behind the persons.

Two persons may be taken in profile, both being turned towards each other in a corresponding degree, or one may be taken in profile, and the other front view, the direction of sight being turned from the first. A union of arms or hands in any way never improves the effect; the independent and separate but well arranged position of each individual, without any dramatic effort, will in the end be found most desirable and agreeable. Of course these remarks do not obtain in the case of man and wife, or mother and child, where it is but natural to expect expressions of affection or dependence; it likewise does not apply to those cases of art which express the character of fear, anxiety, and care.

What is applicable in the grouping of two persons is equally so for more, to which must be added some conditions to be followed with every individual added to the group.

The best plan to proceed with five or more persons is, to arrange them into smaller groups, according to some definite conditions; that is, to combine them into groups of two and two, while one, the odd person in an odd number, is made the principal person in the tableau, and is somewhat isolated, or placed independent of the others, while the smaller groups of two are so situated with respect to this one as to present the most agreeable and striking effect. This is applicable for families and historic groups, only in the first both parents should be kept together in the same auxiliary group.

A special or particular rule to be followed in such grouping is almost impossible, since nearly every case presents something peculiar and different from every other, in other words, analogous cases are the exceptions; all that can be done in the premises, then, is to give general directions with reference to complex grouping.

Above all things giving the image a disproportionate breadth must be avoided, whence it is necessary to seat some of the members of the group, and to place some standing behind these first.

In this connection the size of the persons must be taken into consideration, since very tall persons, for example, placed behind short individuals sitting, will appear at great disadvantage, and produce a disagreeable effect, whereas it becomes such to be seated in front. Children and small persons are placed in the first row between those seated, and very small children find their proper place upon the knees of their parents.

The position of the head is subject to the rules already given for the arrangement of a single person, the same with regard to the arms and hands, these last, to give the best possible total effect, must be placed in the background and concealed as much as possible. Both hands of all persons in a complex group should never be visible.

As a general rule, the direction of sight of all is centred

* Continued from p. 252.

upon one object; but what is nothing less than natural and, consequently, beautiful, is to allow each person in the group to direct his sight in the direction of his particular position, whatever that may be, without distortion; the only thing to be guarded against is, that no one elevates the direction of sight too high.

It must be remembered that the observations made in this article, with regard to grouping for family or social portraits, fail, and are not applicable, whenever an artistic, dramatic, musical, or other society, is to be photographed. In such a group the principal arrangement of the different characters, and their acts and calling, have but a distant analogy to that which harmonizes with mankind generally. All that can be given in the form of a rule, to serve as a guide for the photographer, is to place all the individuals at the proper distance, so as to obtain the sharpest possible image, which not only smoothes the difficulties before him, but, in fact, furnishes the most desirable, life-like, and faithful photographs.

Simple as it seems to photograph groups at rest, all pedantry must nevertheless be avoided. Nothing seems more ludicrous than to see all the members of a group present the same stereotyped look and attitude, and a group photograph is valueless when every individual portrait has the same posture, giving a stiff appearance to the whole.

Only individual talent, personal industry, artistic perception, and practical attention to details can hope to master obstacles, remove all imperfections, and produce the most pleasing results.

Correspondence.

A TEMPTATION TO PHOTOGRAPHIC TOURISTS.

Sir,—Having long waited, but in vain, to see mentioned under the head of "Photographic Tourist," in your valuable journal, by some able writer, a description of the beautiful, romantic, and picturesque scenery of Lynton, Lynmouth, and its vicinity, I now make my feeble attempt to give a few outlines of it, hoping it may be an inducement to some more able person.

It is my impression that this romantic locality is not sufficiently known, valued and visited by my brethren of the camera. Not that it is altogether unknown to fame for every year brings crowds of people from all parts of the world, and it is visited by many of the most eminent artists of the day.

And every one who has beheld its beauties, inhaled its breezes, or bathed in its waters, is eloquent in its praise. I would earnestly call the attention of the photographic tourist who wish to recruit their health, and fill their plate-boxes, with rare and choice negatives to this locality. The sweet magic of streamlet and hill is here on every side, the mountain torrent, with its rocky bed and waterfall, the lakes studded with islets richly wooded, and surrounded with mountains, the sweet inland river bits and savage rocky seashore—all are here. Its glens! what more glorious? Its roaring rivers, foaming over huge rocks! Its thundering waterfalls! Its shady mossy woods and graceful ferns.

They equal in the picturesque beauty of their rocky streams and waterfalls any of the scenes which foreign transparencies have almost led us to believe belongs only to Switzerland; and make us regret that so much of our photographic talent should be expended abroad, when such lovely spots remain unphotographed—almost unknown in these islands.

The far-famed Valley of Rocks is about a mile west from Lynton, and is generally the scene first thought of. There are two roads to the valley—the one a carriage road, the other a path round the cliff called the North Walk. The latter is considered the best by which to gain the most impressive entrance to this stony combe. It is one of the finest terrace walks imaginable, which, for beauty and grandeur of scenery, may challenge England,—or, I may say, the world. Lynmouth and the sea lie 450 feet below; into it a stone may be thrown, so precipitous is the hill; to the right are Countisbury Hill and Foreland, the valley of the East Lyn, and Lyncliff, with the summer-house on its summit. With a suitable lens and camera, a magnificent view of it can be taken. To the left is the open sea at the mouth of the Bristol Channel; and Wales 21 miles across, the water lies in front. On a clear day the Welsh coast, with the counties of Pembroke, Carmarthen, Glamorgan, and Brecon is distinctly seen.

Proceeding onwards, the first terrace of rocks we come to is called the Devil's Chimney Rock, and Moddle-gate Rock; of the latter a pretty view may be taken for the stereoscope.

As you move on under masses of rocks, in all kinds of fantastic shapes, hanging threateningly some 500 feet or more above you, and terrific precipices below you 450 feet into the sea. Where you behold no gentle wavelets ripple over the sand, but sturdy Atlantic billows rolling in from the far north, come bounding over the stony strand, and leaping high into the air, as they strike against the projecting masses of rocks, mingle their thunder discordantly with the shrill screams of the sea-gulls hovering in thousands around.

> "So wonderous wild, the whole might seem
> The scenery of a fairy dream."

We next come in sight of Castle Rock, which gives a beautiful artistic picture, with the surrounding hills.

But no description in words, no pictorial representations can give justice to the wild grandeur of the scenery; it must be visited to be duly appreciated, and if once seen can never be forgotten.

The very top of the centre rock, overhanging the sea, called the Castle Rock, from some supposed resemblance to a castle, may easily be ascended by going up the craggy steep before you. From this path a good picture can be taken of rugged-jack, with entrance of north walk. On various parts of the rock there are a great number of stone seats and tables, and these are a great resort for picnics in the summer season. You ascend the very summit by going up a stony staircase; the view it commands is very extensive. "Imagine a narrow vale between two ridges of hills, somewhat steep: the southern hill turfed; the vale which runs from east to west covered with hugh stones, now rising in picturesque crags and fragments of stones among the ferns that fill it; the northern ridge completely bare, excorated, of all turf and all soil, the very bones and skeleton of the earth; rock reclining upon rock, stone piled upon stone, a huge terrific mass. A palace of the pre-Adamite kings, a city of the Anakins must have appeared so shapeless, and yet so like the ruins of what has been shaped after the waters of the flood subsided."

After quietly surveying the scene around, the grim, desolate gorge on one side, the sea so far, very far below on the other, the awful giddy depth beneath you behold the foaming billows rushing in like wild horses, and all around rise giant cliffs perforated with deep mysterious caverns.

A pretty stereoscopic view may be taken of Duty Point, with the great promontory of High Vear in the distance, by taking the west wing of the Castle Rock in the foreground.

On the south side of the hill facing this rock is a perpendicular mass of rock standing out from the side of the valley like a ruined tower, the layers resembling a pile of huge double Gloucesters, which has from time immemorial been called the Devil's Cheesewring or Cheesepress. As a close object it gives a good picture. There is a tradition that a party of Danes, who had landed on the coast, were overtaken and slaughtered in this wild glen. The legend appears to be confirmed by the fact, that a number of bones have been discovered in cutting a path up the Castle Rock.

I will here mention the romantic yet imaginary "Legend of Lynton Castle," included in a small vol. of the "Legend of Devon," printed at Dawlisle in 1848. In this a castle is given to Lynton, inhabited by the family of Lynton, who are described as having been victims to the Evil One from the year 500 to the middle of the 12th century, when Reginald of Lynmouth began to build a church to his God, on the site of an old abbey at Lynmouth,* whereupon the spell of the Evil One was broken, "the castle fell, the cliff heaved as if in pain, and the terrible convulsion formed the Valley of Rocks."

"The devil was seen scudding before the wind—he had lost his hold on the Lynton house."

The road running eastward through the valley leads back to Lynton, where a general view can be taken of the valley.

Indeed from almost every point of view the Castle Rock and the surrounding rugged cliffs afford a picturesque view.

L.

ROMAN'S MODIFICATION OF TAUPENOT'S PROCESS.

Dear Sir,—I have been pursuing the experiments which I told you I was making with this process, and am now able to communicate reliable results.

The plates are quite as sensitive as ordinary wet collodion.

Thorough washing before albumenizing, and after sensitizing, insures freedom from stains, and does not impair sensitiveness.

The ordinary Taupenot plates, after keeping sensitive at least a fortnight, are as good and as sensitive as those newly prepared.

Those washed after sensitizing with acetate of soda solutions (of course before and after, with water), and finally with a one-grain solution of gallic acid, are a little slower, but will keep a long time.

I exposed one half of a stereoscopic plate, to-day, for 25 seconds, and the other half for 50, when I was giving Fothergill plates three minutes for the same object. The first half was a little underdone; the other quite as well as the Fothergill, and full of half-tone. This plate was sensitized yesterday, and was not washed with gallic acid.

A half-plate exposed just afterwards with a Jamin's lens (front part of portrait combination), 10-inch focus, for one minute and a half, was very nearly done enough. I should have given quite as long or longer exposure to a wet plate; for the object presents much contrast, and the light was very dull. This plate had been washed with gallic acid, and was a month old.

M. Roman has been my tutor, of course; but I depart from his directions,—first, in washing thoroughly, instead of adopting the dangerous plan of leaving a lot of free nitrate on the plate; secondly, in not re-dipping the exposed plate in the aceto-nitrate bath; thirdly, in pouring very hot water over the plate, and then developing (with hot developer) on a holder instead of in a dish, and in renewing the application of *hot* developer, if needed, instead of using it tepid as he then does.

I enclose a description of my manipulation in detail, which, though it is in the main a repetition of what has been often published, may be of interest to amateurs, who yet want an ordinary dry process on which they may most surely rely, and which may be made as rapid as the usual wet process.—Yours truly, J. Galloway Cowan.

[The details, which will prove very interesting to our readers, shall appear in our next.—Ed.]

WHAT THE "ART AND SCIENCE" HAS COME TO.

A Fact for the Commissioners of 1862.

Sir,—Knowing the interest you and your readers take in all matters relating to photography, I am induced to bring before you a few facts which have been recently brought under my notice.

The east end of London, and probably the other suburbs, have lately been honoured by the visits of a peripatetic photographer, who carries with him apparatus, chemicals, mounts, and, in fact, all the etceteras of a photographic establishment.

This gentleman makes house-to-house calls, informing folks that he will, if they please, "take"—to use his own expression—"One on yer for fourpence, or all on yer," viz., the whole family, "for sixpence."

The tempting idea of securing a memento of his family at the above-mentioned cost, proved too much for a weak friend of mine, who, after being "done" by this gentleman, gave me the following particulars of the operation.

After being asked in, his first enquiry was for a dark cupboard; this not being forthcoming, the kitchen was rendered dark by hanging some cloths before the window. A chair was now taken into the garden, and the camera, a quarter-plate, set up. This being done, our photographer produced from his pockets a small gutta-percha bath, a bottle of developing solution, another of collodion, one of fixing solution, and one of bath solution, this latter being a very small one.

All being now ready, a $2\frac{1}{2} \times 2$ glass was taken, rubbed on the operator's coat sleeve, coated with collodion, and placed in the bath, the operator holding it by one corner, but as the solution was not deep enough to cover the plate in one operation, our friend had to lift it out and reverse it. Of course this produced a sharp line across the plate, and the only one in the picture that *was* sharp. The excited plate was now placed in the slide, exposed, and brought back to be developed; but, it not being in mortals to command success, the only appearance was that of a round spot about as large as a shilling. This failure our operator ascribed to the fact that the sun "went in" (into the camera?) at the critical moment of exposure. A second plate coated, exposed, &c., proved a complete success, and my friend enquired if the picture could not be framed. "Yes; but it would be tuppence more." This was paid, and the picture (which I enclose for your inspection) being handed over to its fortunate owner, the photographer "packed up his traps" and departed, having spent rather more than two hours and earned sixpence.

Apologizing for having intruded so far on your space, I remain, &c., J. C. L.

* No abbey and no church having ever existed at that place.

MALT AND TANNIN.

Sir,—Whilst ringing the changes on various preservatives, like many another amateur in search of a photographic elixir vitæ, it occurred to me to try whether malt and tannin would unite, and, if so, whether the good qualities of each would be enhanced or neutralized by the union. I have never been *perfectly* satisfied with either process, much as I am indebted to both.

The advantages of tannin have been fully set forth of late. Amongst others claimed for it, is that of extreme clearness in the shadows, the advantage of which is somewhat doubtful, judging it by the old motto, new version, the proof of the negative is in the printing, which may in one sense be called a truism.

The quality of prints from malt negatives please me, better, on the whole, than those from tannin, but it possesses one drawback, viz., the slowness of development which is tedious beyond endurance.

To come to the practical part of my letter. I tried the experiment of mixing the two fluids, *i. e.*, a 10-grain solution of tannin, and an equal quantity of infusion of malt made with 4 ounces to the pint.

After clearing it through a filter, I applied it in the same manner as tannin.

The advantages anticipated certainly seem to be realised, the negatives have very much the appearance of the malt process, and the development is reasonably quick, in fact, almost as rapid as with tannin alone.

Prints from two negatives are sent for your opinion. Is it worth the attention of the Experimental Committee?—Yours truly, G. S. Penny.

Cheltenham, July 11, 1861.

[The two specimens enclosed by Mr. Penny are in every sense charming pictures; well-selected subjects, good negatives, and excellent prints. They unquestionably prove that the combination suggested is capable of yielding the very best results, and we will bring it under the attention of the Experimental Committee. But we are forcibly reminded of a favourite apothegm of ours, that it is on the man, not the process that good pictures depend. All Mr. Penny's pictures we have seen, are very charming, and every specimen is valued by us.—Ed.]

REMOVING STAINS OF SILVER FROM PHOTOGRAPHERS' LINEN, THE HANDS, &c.

Mix together—

Common alcohol	20 parts
Iodine	1 part
Nitric acid...	1 „
Hydrochloric acid...	1 „

These produce a reddish liquid, which when applied to stains caused *by any salts* of silver, immediately converts them into chloride and iodide of silver, soluble in hyposulphite of soda, and cyanide of potassium.

The effect is especially marked on stained linen; when a black patch is touched with the liquid, by means of a little brush, it instantly turns yellow, with a violet border if the linen has been starched; on washing with the hyposulphite or with the cyanide, the violet tint immediately vanishes, and the yellow spot by degrees. It is well to wash the stained place after the application of the iodized solution to remove the acids, which might produce independent stains by contact with the hyposulphite or the cyanide.

For the hands, the operation is the same, only instead of using a brush, the skin may be rubbed with a piece of rag or cotton.

In applying the solution to paper impressions, greater care is required to prevent the extension of the action to the image itself.

The stains or spots usually present themselves on the skies, or in the backgrounds of portraits; by means of this liquid we may not only completely remove the stains, but lighten the tint of the surrounding space as much as we please.

I have often had occasion to remove skies in this way, and to bleach them, and, in particular, to produce clouds in them, of much better tone than can be done with indian-ink, even by a skilful hand.

The manner in which I proceeded was as follows:—The impression, soaked in hyposulphite, was placed in a porcelain basin kept in an inclined position, the foreground or image upward, and the sky downward; then, taking a small hair pencil full of the liquid, I rubbed the spots very lightly; at first they took a deep blueish tint, which vanished when the same pencil was passed over it, after being dipped in the hyposulphite, which had run down to the lower part of the basin; the stain, which was now yellow, gradually vanished as the hyposulphite was repeatedly renewed in this way, and the paper became white. It is true that to remove these stains I was obliged to bleach the whole of the sky, if they were on the upper part; and to lower its tone if they were near the tops of buildings in the horizon, leaving a stronger tint above, which, however, formed an arch, and increased the effect of ærial perspective, badly rendered by the skies of uniform tint.

The judicious employment of this liquid may also be brought to bear upon the backgrounds of portraits in case of accidental stains, so as to preserve the impression by a skilful repairing.

I have tried to lighten parts which were too black by this means, passing the brush lightly over such portions; the effect is, indeed, produced, but it leaves an uncertainty in the definition incompatible with the front objects, and a hazy tone, due to the bleaching of the supercial fibres of the paper, which, however, might be very useful in bringing down distances too strongly marked—a condition still very frequently met with from the excessive diminution of light at the sides of the picture. A touch with a brush containing a very little of the liquid, immediately followed by washing in hyposulphite, produces wonderful effects in the distances on either side near the edges.

For cleansing the hands, a weak solution of cyanide of potassium will be preferable to the hyposulphite of soda, on account of the persistent odour of sulphur left by the latter; but then care must be taken to rinse the hands well, to avoid the evolution and absorption of prussic acid.—*M. Gaudin.*

Photographic Notes and Queries.

Gallic Acid on Dry Plates.

Sir,—The following particulars may possess some interest, as bearing upon the subject of applying gallic acid to Fothergill plates.

I happened to have by me three plates prepared by the above process, and being anxious to test the principle referred to, I applied a solution of *tannin* to two of them, leaving the third as a test of the value of the application.

The result was as follows:—

The plates washed with the tannin turned out to be good, and produced excellent negatives; the other plate scarcely developed at all, and was covered with a dirty, muddy appearance all over.

This, therefore, argues well for the application of tannin.

I shall be obliged if you will inform me of the chemical difference in the action of tannin and gallic acid, and whether a weak solution of either is more conducive to sensitiveness than a strong solution? whether, in your opinion, gallic is better for the purpose than tannic acid.—I am, sir, your obliged servant,

Tannin.

P.S.—The application of gallic acid to Fothergill plates is not a new discovery, as the same thing was proposed by R. W. Hall, Esq., F.L.S., F.G.S., more than a year ago, and was published by him in a pamphlet on the above process, as well as being referred to in a letter to the *Photographic Journal* about the same time.

London, July 4, 1861.

[The photographic effects of tannic acid and gallic acid might be anticipated to be very similar. There appears to be, however, a decided difference in their results. The former, as used in the tannin process by Major Russell, gives, dense, clean, brilliant negatives, but is very slow; whilst the application of gallic acid to Fothergill plates, not only gives brilliancy and cleanness, but serves, to some extent, as it does in the calotype process, as an accelerator. A three or four-grain solution, in our own experience, is better than a stronger one of either tannic or gallic acid.—Ed.]

Apparatus.

VIGNETTE GLASSES.

Sir,—The use of vignette glasses has been much neglected on account of the expense (although it is but trifling), and many botchy looking pictures have been produced by the introduction of other misapplied apparatus.

The method I have used for some time is this:—Take a piece of white paper, about the size of double crown, upon which gum an oval piece of dead black paper, the size and proportion required, and with a dense collodion produce a negative as follows:—Move the paper backwards and forwards from and towards the lens; copies of the different sizes required may be thus produced with excellent graduation, which will be very good vignette glasses, and when varnished may be placed upon the negative, and printed in the usual way.

Another Style, with White Centre and Black Margin.

Place, this time, an oval piece of white paper upon a sheet of black paper, and take a picture precisely as before. To print, first place this vignette glass upon the sensitive paper, and print the depth required, remove the vignette glass and upon the unchanged white centre place the negative, and having placed the vignette glass which protects the margin in its place, proceed to print. This gives a vignetted picture on a tinted ground, whilst all the whites in the portrait itself are kept pure and clean, that of the paper is much lower in tone, giving an effect of great brilliancy to the picture.

If the centre of this vignette glass is not sufficiently intense, paint over part of the centre with gamboge, and shade off the edge.

I have also a revolving background upon the same principle now in progress. Geo. Owen.

Solihull.

Talk in the Studio.

Imitations of Cameos.—Photographs of cameos printed upon fine negative paper, gummed upon the concave side of brooch glasses, are now being mounted as artificial cameos, and very pretty they look.

Photography and the Telegraph.—The use of the electric telegraph for private purposes amongst commercial houses is becoming general. The first application of it of which we have heard in aid of the ready transaction of photographic business has recently been made by the London Stereoscopic Company, who have just a had wire fixed between their house in Cheapside and their printing establishment at Camberwell, the exigencies of a large business in the production of *carte de visite* portraits, rendering such ready communication desirable.

Alkaline Gold Toning.—We are glad to observe that the alkaline gold toning process, which has hitherto not been practised much in the United States, is beginning to be recognized by our American brethren, as superior to the old hypo and gold bath. The Editor of the *American Journal of Photography*, says: "The independent gold toning process is rapidly taking the place of the sulphuring old hypo nuisance, and people now have a fair prospect of procuring photographs from a majority of the galleries, which will last a few years at least. The new toning process requires a little more judgment and practical tact than the old method, and this fortunately; photographers need difficulties, whereon to sharpen their wits. When the toning process is thoroughly understood, however, it is astonishingly simple and easy; it is preferable on every account.

A Hint to Farce Writers.—We were somewhat amused lately with an incident narrated by one of our principal London photographers. At a portrait establishment, in which a very large business is conducted, it is the custom to number each negative with the number of each receipt, and to place the same order under the same number in the day-book. Through the culpable carelessness of the gentleman to whom this business was confided, these numbers became a source of no small confusion, and, as will be seen, some mischief. Frequently some charming young girl, sending the number of her negative and desiring a positive copy, would receive in lieu thereof a portrait of some ancient lady of the most unattractive appearance; or some smart young buck would obtain a portrait of an old-fashioned, elderly gentleman, &c., &c. The incident, however, to which we would more particularly call attention, is the following:—An elderly lady, recently married to a younger gentleman, so modestly appreciated her own attractions, and so highly esteemed those of her partner, that she grew suspiciously jealous and watchful, eagerly seeking what she so terribly dreaded, as these poor victims of the green-eyed monster will. A friend—highly respected by both husband and wife, and who was on the point of leaving England—was persuaded by the former to accompany him to the portrait establishment aforesaid and sit for a picture. When bidding his friend's wife adieu, he said to her, mysteriously, "If you send to Messrs. So-and-so, of ———, the photographers, for a copy of negative No. 395 (or whatever the number was) and tell them it is the portrait of a friend who accompanied your husband on such-and-such a day, you will have what you have, I hear, often asked for!" The lady did so, and one morning, to her intense horror, received a photograph of a young, pretty, saucy-looking, and evidently fast girl in the most extravagant excess of fashionable attire, in short, "a pretty horsebreaker." We leave you to imagine the scene; the hysterics, the reproaches, and the tears on the one side—the amazement, the useless protestations and explanations on the other side. The photographer was appealed to to set matters right, alas! matters grew more wrong; the gentleman who kept the books being above the power of mistakes. The Divorce Court loomed grimly in the distance, the wife was broken-hearted, the husband frantic; what could be done? At length the friend, who had not reached the vessel before it sailed, returned to town, when all was made clear, and while the wife was the better for her lesson, the photographer saw how important to his interests was the proper keeping of his books.

To Correspondents.

Homo.—Equal parts of iodides of cadmium and sodium, say two grains of each, and half-a-grain of bromide of cadmium, will give you a collodion that ought to remain unchanged, or improved, for 12 months after iodizing, if everything else is in proper condition. We have collodion that has been iodized upwards of that time, and is as sensitive as the day it was mixed. In making proto-nitrate of iron, we prefer the nitrate of baryta. You do not state what iodides and bromides are in your alcohol, but in any case it would be scarcely worth the trouble of getting rid of them for the value of two or three ounces of alcohol.

Gulliver.—Transparencies are printed on glass, not on paper, and several articles on the subject have recently appeared in our columns. Paper prints, produced in the usual way, may sometimes be used as transparencies for some purposes, after they have been waxed; but they are not comparable to transparencies on glass.

G. R. M.—The white spot appears to be caused by the contact of some acid. We met with such a one the other day from a particle of citric acid coming in contact with a print during the washing. The dark spots appear to be caused by the contact of nitrate of silver with the print before the hypo is washed out of it. They would not show until after the picture was exposed to the light, when they turn the dirty brown now exhibited. Other causes might produce them, but these are the most likely.

An Old Subscriber.—You may try the addition of iodine to your old bath containing acetic acid. If it fog, however, as you describe, it probably contains organic matter, which you may endeavour to precipitate by sunning, and then add the iodine. Perchloride of iron is usually prepared by dissolving the peroxide in hydrochloric acid, or it may be produced by heating iron wire in excess of chlorine. You do not state for what purpose you require it, nor whether you are accustomed to chemical manipulations.

X. Y. Z.—The gallic acid solution should be about three grains to the ounce, and is poured on immediately after the last washing. The exposure of a Fothergill plate, with the lens and stop named, would, of course, vary with the kind of object to be taken, and the nature of the light. Perhaps an average of thirty seconds might be named, varying, in a very fine light, to as little as fifteen seconds, and increasing to a minute or upwards. We are not fond of changing bags or hoods for our own use. Squire and Co. have a convenient hood. There are also changing boxes, which are less troublesome. But least troublesome of all is a series of double backs, all filled with plates. We are glad you so highly approve of the lenses we recommended. Probably next week.

Charles Scarfe.—The primary evil is in your glasses, which are not chemically clean, and the dirt causes the metallic reduction of which you complain. Your bath is probably in a condition which favours this effect, and as it is an old one, most probably contains an excess of organic matter, which is very detrimental to the production of good positives. Add a little oxide of silver to it, and expose it to the sun. Then filter and add sufficient acid to make it work well.

E. M.—The best method of lighting a chased silver cup is to place it in a position where it will have a diffused light all around it, but a little stronger on the side where the inscription is. Give a long exposure, with a bromo-iodized collodion, and iron-development, you will thus get it out much more softly and harmoniously than by a short exposure, which would give the lighted parts very dense, and the shadowed parts very black. A transparency on glass much more adequately represents the colour and texture of silver than does a paper print. We were from home when your letter arrived, and this will reach you sooner than we should have time to write privately.

Acetic Acid writes as follows:—Sir,—The meetings of the Photographic Society are so much occupied by the quasi-scientific gentlemen, who are fond of delivering themselves conspicuously on all subjects, whether they understand them or not—artistic questions not excepted—it occurs to me that a stuffed gorilla, placed in some corner, might serve, *en pendule*, to cut short some of the bickerings, and thus save much of the time of the meeting, and spare us a considerable amount of twaddle. [The "stuffed gorilla" to which our correspondent refers, will be unnecessary, since a provincial contemporary has secured a specimen of the genuine animal, alive and foolish, as may be seen in a recent number.]

T. P. E.—We do not know of a dark box in existence such as you desire. We have described from time to time various dark boxes and tents, and shall continue to do so. Probably a combination of the points of those you will find already described in our columns, would meet your case. We prefer the boxes with sleeves to any arrangement which envelops the head.

A. Adams.—We have not met with any similar spots before; but we are not sure that they will grow any worse and ruin the picture as you suppose. Try filtering the toning and fixing solutions. We should in any case advise you to omit the acetic acid from the fixing bath, as it will assuredly slightly decompose the hypo, and cause sulphur toning in a greater or less degree, thus endangering the permanency of your prints.

Ashford.—Your prints give great promise, that containing the water has no faults of manipulation. The others are a little under-exposed. Go on practising in the same direction, but choose better subjects: these have very little pictorial value. Your lens ought to cover better and give more depth of focus; try the next size smaller stop.

Economy.—The manipulatory part of albumenizing paper is generally very troublesome to beginners. The minute bubbles would be more easily avoided if the albumen were more limpid. Keeping for a few days would make it so. To keep the paper from curling up breathe upon the back of that part which curls up. This will often make it lie flat at once. Several excellent formulæ for preparing albumenized paper have appeared in our pages. You will get good results by the formula you name, if you omit the ammonia. That is in our opinion entirely a mistake. Some very good authorities recommend the addition of acetic acid, and we believe professional albumenizers often use it. It will certainly make the albumen more limpid, and, we believe, add to the brilliancy of the print. The presence of the ammonia will materially retard toning.

An Amateur.—India-rubber gloves may be purchased which will keep the fingers clean; or india-rubber finger-stalls will, with care, answer the same purpose. We do not like such things ourselves, remembering the adage about the "cat in gloves." With moderate care there is no need to stain the fingers seriously. The best method of avoiding it, which we know, is to use a piece of mackintosh cloth, about a foot square, in the left hand, and hold the plate, whilst developing with it, between the finger and thumb, as a waiter would hold a hot plate with a napkin. By this method stains may be quite avoided, as it protects the whole hand.

H.—We have no intention of noticing such puerilities. Nothing would delight the proprietor of the Journal in question more than that we should so far dignify his paper as to think it worthy of resentment. We are forcibly reminded of the "fantastic tricks" of the "angry ape" to which our great dramatic bard refers. Our time, thought, and space, are engaged by more important matters.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 151.—*July* 26, 1861.

THE REV. J. LAWSON SISSON'S RAPID DRY PROCESS.

Some weeks ago we announced to our readers that the particulars of an extremely rapid dry process had been communicated to us by the Rev. J. Lawson Sisson, and that the only condition attached to the publication of all details was that we should first try it thoroughly ourselves. We have done so, with varying success as to results, but always with considerable rapidity as regards exposure. It has also been tried by several of our friends: the results we shall state in due course.

Before proceeding further we will give the details of the process, and for exactness we will first state them in Mr. Sisson's own words. The manipulations in this process are very similar to those recommended for the preparation of tannin plates. Mr. Sisson says:—

"I used Ponting's collodion, ordinary nitrate of silver bath, washed the plates in two or three baths of water, poured over carefully a small quantity of the liquid, and then raised up to dry in a warm room, just as in any other dry process."

The preservative solution is made as follows:—

"If you take one ounce of ordinary gum arabic and dissolve it in one ounce of water by gentle heat, and then by degrees add one ounce of water to it in which has been dissolved some common borax, biborate of soda, you will have a most remarkable mass, twice as large and twice as stiff as the first solution. This is, or ought to be a well-known fact. Now keep adding water in which has been dissolved as much borax as it will take up (it dissolves a very very small quantity) until the liquid is almost as thin as water; then add a small quantity of spirits of wine to the solution, which will no longer precipitate the gum as before, but absolutely rather thicken the solution, as careful experiment will show you."

The development Mr. Sisson states may be effected either with pyrogallic acid and silver, or iron and silver, the latter giving the most rapid results.

The general characteristics of the negatives obtained by Mr. Sisson were, as regard softness and delicacy, as nearly as possible similar to those obtained by wet collodion. The tone is very fine for transparencies, being of a rich warm brown black not requiring any toning. The plates have in Mr. Sisson's hands kept for months without deterioration, and the preservative solution was perfectly good at the end of twelve months. All the prints we have seen from Mr. Sisson's, vouch for the excellent character of the negatives.

In following out the above instructions for preparing the preservative for our own experiments, we made a solution which contained, when completed, six grains of picked gum arabic, from two to three grains of bi-borate of soda, and twenty minims of alcohol to each ounce of water.

We sensitized several stereo plates, in some of which a bromo-iodized collodion was used, and in others a simply iodized sodium collodion. On removal from the ordinary nitrate bath each plate was placed in a dish of distilled water, and remained there until another plate was prepared, when it was transferred to another dish of common water, and after remaining there until another plate was coated, was finally carefully washed with about a pint of common water poured from a jug. Sufficient of the preservative was now poured over the plate at one end. and suffered to flow off at the other; and then a second portion was poured on at that end. and after flowing over the plate, drained off at the opposite end. The plates were then reared up against the side of a large jug containing hot water and dried.

The plates were exposed within a few days, some in a moderate diffused light, others in weak sunshine for various periods from two seconds to ten; using a Dallmeyer's stereoscopic lens and three-eighths stop. Some were developed with a solution, containing fifteen grains of iron, and fifteen minims of acetic acid to an ounce of water, to which three or four drops of a twenty-grain silver solution were added; and others with a two-grain solution of pyrogallic acid. The results varied, the best negatives being those prepared with the simply iodized collodion, and developed with iron; a five seconds' exposure in a weak sunlight giving an excellent negative. Another plate, which received ten seconds' exposure in diffused light, developed with pyro gallic acid, yielded a similar picture. The negatives were clean, crisp, and vigorous, black in tone, and in all respects satisfactory.

So far the results were highly satisfactory and promising; but we are bound to add that in several other experiments we were not so entirely successful. Unless the utmost care was used in washing away all the free silver, a tendency to a red fogging was present, which we have noticed on other occasions in plates prepared with gum. In all cases, however, the results were superior in rapidity to most other dry processes, and very little inferior in sensitiveness to wet collodion. The development is almost as rapid as that of a wet plate, and we noticed no tendency to blisters, or danger of losing the film.

The reports of the gentlemen who have tried plates prepared with this preservative vary; but as in all the tendency to fog or stain in developing, unless great care had been used in preparing the plates to get rid of free nitrate, it is quite possible that the cause might be found in some peculiarity of the solution used, which was in all cases from the same bottle as that from which we ourselves found similar results. Some of our friends state that they found the plates not more rapid than those prepared by the Fothergill process, whilst others found less than half the exposure sufficient.

It was our intention to have submitted the process to further experiment before publication; but an unusual pressure of duties has prevented us, and as the season is rapidly advancing, we think it desirable that our experimental readers should have an opportunity of trying it before the summer is passed. In our hands it has justified our hopes of rapidity, and in the hands of the inventor, the Rev. J. Lawson Lisson, it appears to have yielded results of the utmost uniformity, both in rapidity and in the high quality of the pictures produced. To those of our readers, who may be anxious to try the process, we should recommend a little less gum and a little more borax in the solution, and the utmost possible care in washing before applying it. We shall be glad to learn the results in the hands of any of our readers.

MODES OF FIXING NEGATIVES.

Since the practice of using iron development for negatives has become general, especially amongst portraitists, whilst a higher class of pictures, softer, rounder, and more delicate has been produced, we have not unfrequently heard complaints of some little difficulty in obtaining sufficient brilliancy and vigour. As, under these circumstances, every minor addition to the printing value of a negative is of importance, we think it may be just worth while to call the attention to the difference in this respect caused by different modes of fixation. The superior solvent powers of cyanide of potassium, and the readiness with which it is removed from the film by a slight washing, have made it a great favourite with many photographers; but we question whether these advantages are not often purchased at too dear a price. Operators familiar with the positive collodion process, are well aware that the great advantage of cyanide of hyposulphite for fixing glass positives consists in the fact that the image, when fixed with the latter is generally more or less brown or tawny, whilst it is much whiter when cyanide is used. Now in negatives the very opposite conditions are desirable; the brown tint is just that required in negatives, because least permeable by actinic light. It is not an uncommon occurrence to find iron negatives really less repellant of light than the amount of deposit would lead an observer to expect. Where cyanide has been used for removing the unaltered iodide of silver, this is very common, the negative being left of a colour most favourable for the transmission of light. The experiment may easily be tried by fixing one negative with hypo, and another with cyanide; or, what will answer the purpose quite as well, fix a negative with hypo, and then pour over one-half of it a newly-made solution of cyanide of the strength generally used for fixation. It will be seen that the colour of the part submitted to the cyanide inclines to white, whilst that to which the hypo only has been applied is of a decidedly tawny hue.

Another fact should also be remembered, that the tendency of cyanide, especially in a fresh solution, is to attack the image, and destroy the half tone. This tendency is much more apparent with some collodions than others, but we believe it is in most cases more or less present, and however weak the solution may be, a negative unless quickly rinsed after fixing will be in some degree acted upon, the delicate shadows suffering first, and thus robbing the print of much beauty. In another column a letter will be found from Mr. J. C. Leake, to whose attention we had called the advantages of hypo fixing when troubled with some want of vigour in iron negatives. Both the negatives and prints referred to bear out our conclusions. The difference is not very great, but it is unmistakable; and, as an able photographer recently remarked to us, referring to another photographic process, "In aiming at perfection, a very slight improvement is worth a great deal of effort."

The practice amongst first-class photographers varies in this respect. The very best portraitist we know invariably fixes with hyposulphite of soda. Some other good men use cyanide. One to whom we recently mentioned the subject uses cyanide, but always uses it over and over, in a dipping bath, the contents of the one now in use having been refreshed, but never entirely renewed for two years! and are so weak that about a minute and a half are required to remove the iodide. We have noticed this fact, however, that amongst the best photographers we know, cyanide is rarely used except where some intensifying process is used which is applied after fixing, in which case the colour of the film is of little consequence, as it is to be altered by further intensifying.

It is important for those who may have been using cyanide and are disposed to try hyposulphite of soda, to remember that where the latter is used, very careful washing is necessary to remove it from the film, and that, where available, warm water effects this much more readily than cold.

PHOTOLITHOGRAPHS.

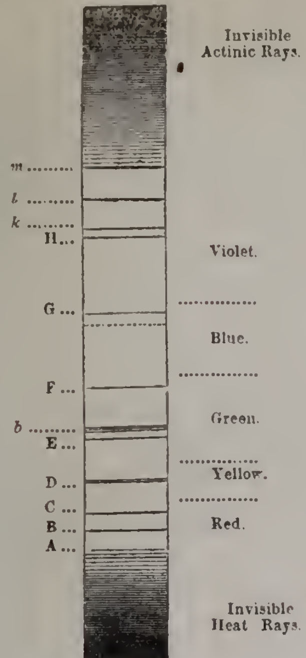
We have received from Mr. Ramage, of Edinburgh, a series of reproductions of engravings by means of photolithography, which exceed in delicacy and beauty all we have hitherto seen. The whole of the subjects are in line, and do not, therefore, in principle, surpass the productions of Col. James or Mr. Osborne, and, indeed, it is probable that the process by which these are produced is of a similar character to the processes of these gentlemen. The manipulation, treatment of the subject, and the results generally, are decidedly the best we have seen. As they are all from familiar engravings we are enabled to judge how far the subject has lost in translation by means of photography, and are bound to state that in many instances, whilst they have gained in delicacy by the reduction in size, they have not lost in any respect. The negatives are about whole-plate size, and comprise—"Uncle Toby and the Widow," after Leslie; "Tartar Banditti Dividing the Spoil," after Sir W. Allan; "The Combat," after Etty; "Cup Tossing;" "The Jew's Harp," after Wilkie; and "The Prisoner of Gisors," after Wehnert; the last-mentioned pleases us most, being a charming transcript of a very charming engraving. There is another specimen in which one of the full-page wood engravings from *Punch* is reduced to a size about three inches square, which strikingly illustrates the value of this process for producing reduced and exquisitely delicate copies of larger engravings. Another peculiarity of the specimens before us is a novelty in the paper on which they are printed, which is prepared with some pigment so as to give a most admirable surface, and materially aids in the delicacy of the results. Whilst many photographers are devoting any amount of effort so as to secure absolutely black tones in their prints, Mr. Ramage, with any colour he may choose at command, has the good taste to choose a black with a decided suspicion of warm purple in it, giving a peculiarly agreeable, warm, velvet-like bloom to the deep shadows.

Mr. Ramage remarks, in a letter which will be found in another column, that, notwithstanding many promising attempts, he has not succeeded yet in producing any subject with half tone sufficiently perfect for public inspection.

Scientific Gossip.

The invitation which we made in our last "Scientific Gossip," to examine by means of the spectroscope any samples of coloured glass with which our readers might desire to glaze the windows of their photographic laboratories, has been responded to by several photographers. Before, however, we give the results we have obtained with these pieces of glass, it may perhaps be as well to refresh the reader's memory on one or two points connected with the spectrum, and the action of coloured light on silver salts.

In our former article we explained the principle of the spectroscope, and stated that by its means a very pure solar spectrum could be obtained at any time, even when the sun was not shining, by pointing the instrument towards a white cloud. This solar spectrum is, as is well known, a luminous brilliantly coloured band crossed with an immense number of sharp black lines of all degrees of visibility. If our readers refer to the accompanying diagram, they will see a very accurate representation of the spectrum, with the principal lines with which it is crossed. At the lower end of all are shown the heat rays; above those, and commencing a little below the fixed line A, are the rays of red which extend upwards to between C and D when the yellow begins. The band of yellow is very narrow and rapidly merges into orange, which at about midway between D and E changes to green. This colour extends in great purity to a little beyond F, when it takes a bluish tinge, and rapidly gives place to blue, which extends upwards, merging into a purple tint at H, until nothing more of the spectrum is seen, unless direct sunlight be used, when the line H and a little space beyond is distinctly visible, and appears of an indeterminate lavender tinge. Beyond this visible point the spectrum still extends, consisting in these highly refrangible parts of the chemically acting photographic rays. Now, although these invisible rays are termed the chemical rays of light, they are not the only ones which act upon a sensitive surface. The photographer makes use of rays of light far down into the visible coloured space. Thus, when the sensitive surface consists of iodide of silver, it is affected by all the rays of the spectrum situated above the dotted line



just beneath the line G in the diagram; iodide of silver being sensitive to the upper half of the blue rays as well as to all above. When the sensitive surface contains bromine there is equally with iodine a definite boundary line of action, the darkening being produced only by the rays above the fixed line *b* (between E and F), forming three-quarters of the green, together with the blue, indigo, violet and invisible spaces.

It is necessary, therefore, that any piece of glass which is intended to obstruct all chemically acting light from the photographic laboratory should be absolutely opaque to all rays above the line *b*, whatever be the intensity of the light which is likely to fall upon it. Very few of the samples of glass which have as yet been forwarded to us fulfil this condition accurately; a few of them being so bad that our wonder is the owners did not long ago find out their worthlessness for themselves.

We will distinguish each piece of glass by a number for the sake of comparison, and in order that they may be identified, will give after the number the initials of the photographer sending them.

1, S.—This glass was described as being prepared with saffron, in the manner described in our number for the 21st of June last. (No. 146, p. 298.) The colour was very pale, and on placing it in front of the slit of the spectroscope it was seen merely to diminish the intensity of the rays above F, still allowing them to pass through. It would therefore afford scarcely more protection than colourless glass.

2, S.—This glass was prepared in the same manner as No. 1, a greater body of colour being on the surface. It was much better than No. 1, but still allowed blue and violet light to pass. A combination of the two glasses almost entirely cut off all the rays which act upon iodide of silver, and it is probable that two glasses as deeply coloured as No. 2 would prove quite efficacious where iodised collodion only was employed. It would, nevertheless, be very unsafe to trust to this glass when employing collodion containing bromine, as it transmits with facility rays in the green, which are capable of acting strongly on bromide of silver.

3, Sphynx.—This glass is of a light green colour, and is quite inapplicable to photographic purposes: it merely cuts off the extreme red below B, and the blue and violet above G, transmitting all the others with facility. Both bromide and iodide of silver would therefore be strongly affected behind it.

4, W.—A deep orange glass, which cuts off all the rays above the line E.

5, W.—A similar piece of glass to No. 4, only slightly differing in tint; it was found to possess the same action on the spectrum. In strong sunlight these two samples of glass seem to allow a faint glimmer of actinic rays to pass, but the amount would not be sufficient to be of any effect in an ordinary dark room, and it could be rendered absolutely safe by using two thicknesses.

6, W.—This glass looks of a dark brown when laid upon white paper, but if held up to the light, appears much lighter. Tested in the spectroscope it was found to exercise a marked action on the rays of light above the line F (the blue, violet and higher rays), but it did not quite cut them off, some being still transmitted. It would therefore be of no value if bromine were employed, and a very unsafe glass to use, except in a weak light, with iodised collodion.

7, W.—This is a similar glass to No. 6, but of a darker colour. It was found to have the same general characters when examined in the stereoscope, as No. 6; but owing to its deeper colour, less of the active rays were allowed to pass.

8, W.—A similar glass to the former two, but much darker. It almost entirely cuts off above the line E; but at the same time it much obscures the intensity of the lower luminous rays. In strong sunshine it was seen that the active rays were still able to struggle through in sufficient numbers to affect a sensitive plate.

The last three pieces of glass are coloured with the same substance, and merely differ from one another in the depth of intensity of the colouring matter. We do not advise this kind of glass to be used, as unless several thicknesses are used it is not safe, and if the colour be deep enough to obstruct all the active rays, so much light is cut off at the same time as to render it unpleasant to work by.

9, C. S.—This is a deep blood-red glass and exercises a very marked action on the spectrum. It cuts off, as with a knife all the rays above the fixed line D. None of the orange, green, blue, or higher rays can therefore get through in the least, and a room might be glazed with any number of square feet of this glass without being thereby rendered unfit for the most delicate photographic experiments. This is the most perfect glass we have yet examined, the only drawback being its dark red colour, which, after working behind it for some time, we have found to be rather painful to the eyes, causing everything for some time after to assume a greenish hue.

THE TAUPENOT (RAPID) PROCESS.

BY REV. J. GALLOWAY COWAN.

Coat with a suitable collodion, that is, one that adheres firmly to the plate after being treated as below described, and set up to dry for the last time. If the sensitized and washed coating shows a tendency to curl up at the edges when drying, doctor the collodion thus:—To one ounce of it add five grains of carbonate of soda, from which all moisture has been expelled, by drying it over a spirit-lamp, shake it well several times in the course of about an hour, and then filter it through blotting-paper, add an equal quantity of undoctored old collodion, and it will be fit for use. The collodion prepared by Mr. Ackland for dry processes, and Mr. Hughes's bromo-iodized, do not need this treatment.

Sensitize in an ordinary negative bath very slightly acid.

Immerse in a dish of distilled water, shake about till greasiness disappears, then wash with about a pint of common water, covering the surface with as much as it will hold, and moving it about as you would developing solution, for a few seconds, then pour down sink; repeat this till the water is all used, then drain and coat with a portion of—

Albumen	4 ounces
Distilled water	2 „
Iodide of ammonia	8 grains
Bromide of „	4 „
Chloride of „	6 „
Liquor ammonia	40 drops.

Let it rest on the plate for half a minute, then stand up to dry. When surface-dry, make quite hot before a fire or against a vessel of hot water.

These plates will keep for months.

When wanted for use, immerse in bath of—

Nitrate silver	35 grains
Glacial acetic acid	30 drops
Distilled water	1 ounce.

Let it remain about half a minute.

Remove and wash as before.

If wanted to keep some time, and to bear long exposure without injuring high lights, cover the surface with

Acetate of soda	5 grains
Water	1 ounce.

Wave backwards and forwards a few times, wash off with water, and finally coat with

Gallic acid...	1 grain
Water	1 ounce.

(Carefully filtered.)

and set up to dry spontaneously.

For rapid pictures expose same time as ordinary wet collodion.

To develop, pour over plate a good quantity of very hot water. Then pour on a portion of

Pyrogallic acid	3 grains
Glacial acetic acid	30 minims
Distilled water	1 ounce.

(Very hot.)

After the developer has thoroughly permeated the surface, say two minutes, pour it off, and pour on a fresh portion (for the sake of having it warm) to which about 6 drops of 10-grain nitrate of silver solution have been added.

When this developer discolours, wash the plate again with very hot water and proceed as before, unless the details are pretty well out, in which case cold water and developer may be substituted. The quantities of pyrogallic acid and silver must now be varied according to the state of the picture. If the detail is out, but lacking intensity, weaken the developer with an equal portion of water, and add more silver; if the picture is wanting in half-tone, use a little more pyrogallic acid, and only *one* drop of silver solution.

Fix in hypo-sulphite of soda, and wash very thoroughly.

For ordinary dry-plate sensitiveness, expose about six times as long as wet collodion, soak for a few minutes in cold distilled water.

Now pour on cold developer of the strength given above, adding no silver for at least two minutes, and then only one or two drops. Have the courage to keep back the silver till the picture won't come out without it, and you will avoid the deposit which is such an eyesore to the photographer, and which, though it may generally be rubbed off without injuring the negative, occasionally makes you the perpetrator of irreparable damage.

In my hands (and they are somewhat clumsy) plates treated in this way always yield negatives free from stains and blisters, and when they have been sufficiently exposed, full of half tone.

ON GOLD AS A PHOTOGRAPHIC AGENT.

BY MR. DAVIES.*

Pure gold is of the specific gravity of 19·5, and its atomic weight or combining equivalent is 197. It is almost invariably found in the metallic state, but occasionally contaminated with silver and copper: and in this state its only photographic use that I know of is that of being combined with the profits of some dealer in cameras, lenses, or photographic materials. I am sure most of you will be too familiar with its use in that direction to need any light that I could throw on the subject. Indeed, I believe it is more extensively used in that way than in any other, especially by amateurs.

Although in the metallic state, it is perfectly unoxidizable in atmospheric air, still there are various modes in which it can be made to succumb and unite to the other elements. Thus it can be made to unite with oxygen in two proportions. The suboxide $Au\ 2\ O_2$, and the sesqui or peroxide called auric acid $Au\ 2\ O_3$. Again, with ammonia, to form fulminating gold—the ammoniacal oxide—which is occasionally formed in making chloride by the hydrochlorate of ammonia method, which I advise you to avoid. Again, it unites with sulphur in two forms, corresponding with the oxides—disulphuret $Au\ 2\ S_2$, and the sesqui-sulphurite $Au\ 3\ S_2$; and with chlorine we have the sub or dichloride, which is quite different from our chloride, being a yellowish non-crystalline body, quite insoluble in water, and totally unfitted for photographic use; while, with the addition of one atom more of chlorine, we have the sesqui, per, or terchloride, or, as we call it shortly, chloride of gold, $Au\ Cl_3$, the additional atom of chlorine making it a crystalline body in dry air, and a moist mass in ordinary atmospheric air. Thus you have the key to the sealed tubes in which it is usually sold commercially. It has become, with this additional atom, soluble in water, alcohol, and ether; and such an affinity has it for ether, that you may extract every particle of it from an aqueous solution by means of ether alone. This etherial solution, by-the-bye, has the quality of gilding bright iron or steel by simple immersion only. It is with this tractable salt that we, as photographers, have mainly to do, as without it we could have no phosphate, citrate, or other of the exquisite and safe-toning baths we now use, and would have no resource save in sulphur—which we have happily been forced to learn, by bitter experience, the uselessness of—and perhaps platinum, which is comparatively powerless, and does not produce the fine tones of gold, besides being very much slower.

If we, as a young and practical society, had followed the natural routine, we should have had a paper on positive printing before one on toning, and it would have saved both you and I some trouble; as I must be allowed to say a few words on that subject before coming to the question of toning, and on gold as the agent.

Whatever may be the mode of producing negatives—whether the Fothergill of Mr. Burns, or the wet collodion of Mr. Nichol—we are all agreed as to the use of the negatives made, viz.:—to assist in producing good prints; and I am of opinion that the introduction of alkaline gold toning has caused most photographers to be more careful in the production of them, as it is a truth that, while a fair print might be got from a poor negative by the old processes, you cannot get anything like the same kind of quality from the alkaline gold process unless the negative be good, the prints requiring to be fully and deeply printed. I would also say, don't spare the silver. If you buy your paper ready albumenized, you may safely calculate that it is salted with at least ten grains of salt to the ounce. I think this too much, and never, when albumenizing, use more than from three to five: using ammonium by preference with this quantity, and with a 50 to 60-grain bath. you will get as fine prints as with an 80-grain bath and 10-grain salting solution.

In reference to the theory of toning by gold, my opinion is, that the action of the gold in the bath, in whatever way it may be made, whether by simple chloride, with a dash of alkali, or phosphate, or citrate, is similar to, if not identical with, the action induced by the galvanic battery: and that the gold is deposited on, and partly substituted for, the silver with which the paper was originally covered. Although I have not tested it yet, I feel certain that an appreciable

* Read at the Meeting of the Edinburgh Photographic Society, May, 1861.

amount of silver could be recovered from old toning baths if they were kept, resulting from the substitution of the gold for the silver previously on the paper.

I may mention here, without in the least attempting to claim any originality in the matter, that with the exception of a short erratic chase after Mr. Sutton's *sel-d'or* bath, when using the ammonia nitrate paper, I have never used any other than an alkaline gold bath, which is now a new discovery, and I believe that many others can say the same. I have now used it fully four years.

From the many forms which adulteration and short weight and measure assume, I hope I shall offend no one by saying that, as usually sold in the shops, you rarely if ever get the full value for your money. Tubes with a warranty of 15 grains of pure chloride are almost unknown; and it was this, together with not caring "to pay too much for my whistle," that first called my attention to the task of trying whether I could not cheapen its cost to myself. After trying the dissolution of various pieces of metal, from a half-sovereign to some old jewellery, I tried some gold dust in that state of minute sub-division in which it is brushed off the gilding of picture and mirror frames during the process of gilding them. Perhaps my business led me to it; at all events I found that the cheapest and best material for making it. It is usually sold for £3 per ounce, instead of £4 for sterling, or £4 to £8 for pure gold (which by-the-bye you must use for the hydrochloride of ammonia method of making chloride). It is of fine quality, nearly if not quite as fine as sterling; but in that state is only fit for the melting pot or for this purpose. To use it I proceed thus:—I take, say 70 grains of this material, which costs 8s. 6d., and which, with the addition of six pennyworth of acid, makes 100 grains at least of chloride, at a cost of not more than 1½d. The mode of doing it is this:—Take five parts of hydrochloric acid, three of nitric, and one of water. Mix and add the gold. If slow of dissolving, gently heat it, and in two minutes it will be ready for the next step in the process, as you see. It is now, however, impure, from the mixture of silver and copper alloy, which has also been dissolved, and there is sure also to be a surplus of acid used; therefore we must get rid of both, which is done by one operation, by simply neutralizing by carbonate of soda, which changes the silver and copper to carbonate of those metals, and leaves a residue of chloride of sodium in the gold, which is of no consequence to the toning powers of the article. If for immediate use, slightly over-neutralize it and filter, and you may use it at once, as I will do; if wanted to be kept in the solid state, the acid is driven off by evaporation and heat; if fluid, by determining your quantities you can, by adding water to make it, say one drachm to the ounce, keep it in that state. It is best to be kept in the dark. I have purposely omitted giving strict rules as to quantities, as you may vary within very wide limits; and would only advise, as you are never sure of the commercial strength of your acids, to always have a full allowance of hydrochloric acid, as it is the free chlorine which determines the dissolution of the metal.

Mr. Davies then proceeded to dissolve a quantity of the gold, from which, in a few minutes, he toned several albumenized prints. After which he stated that, had time permitted, he should have shown the other methods of using the material made, including the citrate of gold process—which is very beautiful and effective, but very wasteful of the chemicals, as they do not remain in action for any time—and also the chrysotype, a process which depends for its results on the reduction of a persalt of iron into a protosalt, but hoped that time would be found for that some other evening.

Dictionary of Photography.*

Pyroxyline—*continued.*—Amongst the varieties of soluble cotton, produced by the action of acids of different strengths and combined in different proportions is one to which Mr. Hardwich—who has given, perhaps, more attention than any other person to the manufacture and chemistry of pyroxyline—attaches considerable importance: we refer to that which he distinguished as being *parchmentized.* In the course of his experiments he observed, that pyroxyline which was made from cotton wool or bibulous paper which had been submitted to the parchmentizing action of dilute oil of vitriol, possessed distinct and desirable characteristics.

It may be desirable to explain, in passing, that sulphuric acid, diluted with half its bulk of water, has the property of converting unsized paper into a substance having nearly all the qualities of parchment, especially its toughness and closeness of texture. Pyroxyline made from this paper exhibited similar characteristics, and gives a collodion which is thus described:—

"The first noticeable effect of the previous parchmentizing, will be an increased fluidity and freedom from structural lines. The collodion when poured upon a glass sets very rapidly, and with such firmness that the finger may be rubbed backwards and forwards without disturbing it. The film on lifting from the bath soon becomes partially surface-dry, and repels developers or fixing agents; when washed with water and dried, it forms a dense and highly-varnished surface nearly impenetrable by liquids. The moist film after development with pyrogallic acid and fixing, appears unusually *tough*, and will bear pumping on without injury. It is also very contractile, and tends to draw itself away from the edges of the glass. When pushed aside it can be pulled back again like the finger of a glove. The fixing agent never removes any portion of the image from this collodion because the iodide of silver is *in* the film and not only upon its surface."

Having found these desirable qualities, it next occurred to Mr. Hardwich to secure the same results in one operation, by largely increasing the amount of oil of vitriol in the mixed acids. He found that the parchmentizing action of the sulphuric acid took place at once, before the nitric acid commenced its action of converting the cotton into pyroxyline, and that the cotton prepared in the mixed acids having a large excess of sulphuric acid, had similar characteristics to that which had been submitted to the parchmentizing influence of sulphuric acid before immersion in the nitro-sulphuric acid.

The manipulations for producing this pyroxyline we shall give in Mr. Hardwich's own words as given in the last edition of his "Photographic Chemistry," remarking, in passing, that the fullest treatise on the chemistry of the different samples of pyroxyline is to be found in that work. The cotton he prefers is the finest American grown cotton, which is gently boiled for two hours in a solution containing two ounces of potash to a gallon of water, and after thoroughly washing and drying is fit for use; the washing being intended to cleanse the fibre from oily or resinous matter with which he finds it often coated. Great care having been exercised in getting the acids pure of exact specific gravity, he takes as follows:—

Oil of vitriol, 1·845 at 60° Fahr.		18 fluid oz.
Nitric acid 1·457 at 60° Fahr.		6 fluid oz.
Water...		5¼ fluid oz.

"Pour in first the water, then the nitric acid, and lastly the oil of vitriol; obtain a perfect admixture by stirring, and take the temperature. If the thermometer rises to 165° Fahr. or 170°, the acid must be allowed to cool until it stands exactly at 150° Fahr. Then immerse the cotton in pieces well pulled out, and weighing thirty grains each, continuing to put them in singly until *ten* have been introduced, making 300 grains in all. This operation, together with the pressing against the sides of the vessel, etc., to be alluded to again presently, will occupy about a minute and a half, after which the vessel may be covered up and left for nine minutes. The process is complete in half that time, but the extra five minutes, although producing a little more solution of the pyroxyline, and consequently diminishing

* Continued from p. 303.

the weight of the product by about 15 per cent., produces a collodion which is less likely to show glutinous markings upon the glass, or to dry up speedily and repel the developer. Lastly, take out the pyroxyline in one lump with glass spatulas; squeeze out as much of the acids as possible in a porcelain capsule, and dash the whole into a large quantity of water.

"With regard to the temperature at which the pyroxyline should be made, the author worked at first at 140° Fahr.; but was eventually induced to raise it ten degrees, in consequence of representations that the collodion was somewhat deficient in fluidity. This increase of temperature, however, assists in generating traces of a body (probably nitro-glucose) which causes the collodion to lose its sensitiveness more rapidly after iodizing.

"An experienced person will be able to judge on lifting the cotton out of the acid, whether he has hit the right point. If, on attempting to lift out the whole mass of pyroxyline at once with the glass spatulas, it seems rather small in quantity and very rotten, so that little pieces break away and are left behind in the acid, then the temperature was too high, or the acids too weak, and in repeating the operation the water must be diminished by two or three drachms in the quantity of acid given above. If, on the other hand, the mass of pyroxyline appears large, sticks well together, and shows no tendency to tear, either the temperature has fallen several degrees, or it will be advantageous to work with a few drachms more of water.

"Whilst the pyroxyline is washing in the tray, it is still more easy to judge of its quality; for if the ten separate pieces, in which the cotton was originally weighed, are seen floating about, and can be separated and counted, the acids were certainly too strong; whilst if there be an evident aspect of commencing solution—a piece of cotton here and there scarcely changed, but the others in a measure broken up, and tearing easily under the finger,—the operation is probably successful; but when the whole is so mixed up together that nothing but fragments of the ten pieces can be detected, then the acids were too weak, unless the temperature was inadvertently allowed to fall.

"It takes twenty-four hours to ensure the proper washing of the pyroxyline, even in a slowly-running water which contains a portion of chalk; this carbonate of lime evidently acts in neutralizing the acid, and bubbles of carbonic acid gas form, which bring the cotton by degrees to the surface of the water, and keep it floating.

"After a thorough washing, the pyroxyline is squeezed in the hand, and then picked out to dry upon a cloth. A boy performs this part of the operation; and after a little experience, he can tell easily whether the material was properly made, partly by the extent of surface which it covers upon the cloth, but more easily by the readiness with which it tears under the fingers. If it resembles the original cotton in appearance, and feels strong and tough, the amount of water in the acids must be increased: but when it breaks up into little bits, it is correctly made, or else is somewhat too weak, in which case the fragments will mat together, so as to increase the difficulty of picking them out. As the pyroxyline dries upon the cloth, it will be well to examine it and give directions accordingly, separating any piece which appears less acted on than the rest; this piece was probably the piece put last into the acid and left at the upper part of the liquid.

"Two or three days' exposure to the air will render the soluble cotton sufficiently dry: but it is convenient to finish it off on the hot steam-bath before described, and the temperature in which must not be allowed to rise higher than 120° Fahr. When dry, proceed to weigh it in the scales, and form your estimate of its value accordingly. A long experience tends to show that, supposing nothing to be lost in the washing, the weight of the resulting pyroxyline is a certain and safe guide in this process, and it is always possible to tell what the quality of the collodion will be by using the scales. If 300 grains of cotton yield 450 grains of pyroxyline, it is certain that complaints will be made of the resulting collodion being thick, and giving streaky pictures: four or five additional drachms of water in the above quantity of nitro-sulphuric acid will be the remedy. When the weight of the pyroxyline is the same as that of the original cotton, viz. 300 grains, there will be a sediment on dissolving it in the mixed ether and alcohol; nevertheless the collodion, although lessened in quantity, will be good,—very limpid and structureless, with great adhesion to the glass, less tendency to markings of all kinds, and considerable softness of negative with sensitiveness to dark rays. The chance of spots, however, is peculiarly great with this collodion; for if the smallest particle of dust touch the film, it will almost certainly arrest the development, and produce a transparent circular mark.

"The weight which on the whole appears to be best is 375 grains, that is to say, exactly 25 per cent. of increase; this gives sufficient fluidity of collodion, and at the same time leaves very little sediment in dissolving.

"The above facts are quite reliable, since they have been verified by repeated observation, extending over a long time. It must, however, be distinctly understood, that the weight of the pyroxyline can be taken as a criterion of quality only under the conditions stated,—the fibre of the cotton must be cleaned by potash *and quite dry*, the nitric acid nearly free from chlorine, the time of immersion always the same, and, most important of all, the temperature correctly ascertained, otherwise the weight will be so variable that nothing can be deduced from it, and the cotton will be considerably acted on, even when the acids are strong enough to produce an explosive variety of pyroxyline. The whole process, in fact, requires care, because it is conducted with the maximum quantity of water, and at a high temperature. At least 20 per cent. of the pyroxyline is dissolved in any case; and the acids having once begun to act, will readily destroy the remaining portion of the fibre, if an error be permitted.

PHOTOGRAPHY AT LITTLE PEDLINGTON.

Letter the Second.

Strange Remark made by an Ignorant Londoner.—First Meeting of the Little Pedlington Photographic Society.—Rash Speculation.—Quotation from "The Pedlingtonion Journal."

Sir,—In fulfilment of my promise, I shall now enlighten the listening world with my brief historical sketch of the photographic art and science as associated with Little Pedlington. Before commencing this task, however, I wish to refer to certain remarks made by a gentleman of your town of London to a friend of mine, who has recently returned to this, his native place (and a very poor opinion of the former, as compared with the latter, has he).

"Sir," said this gentleman, "*there is no such place as Little Pedlington.*" (! ! ! !)

"What!" exclaimed my Pedlingtonian friend; "no such place? why, you will deny my own existence next!"

"I believe," said this strangely ignorant and shameless Londoner, "I believe that Little Pedlington is only to be found in the littleness of vain and ignorant people, and in their peddling ways of making an immense fuss about trifles. I believe, in short, that while Little Pedlington, as thus represented, may be found in every department of learning, and in every phase of human life, Little Pedlington, as a town, cannot be found anywhere."

Of course, I should only insult my readers by supposing them to be as ignorant as the above benighted individual, should I attempt to prove that Little Pedlington, "*mine own romantic town,*" * *is* situated in this or that county, *is* so many miles from this, and so many from that place, *is* reached by the coach, which runs with tolerable regularity between Little Pedlington and the Squashmire Gate Station three times a week, &c. How absurd would my doing so

* Sir Walter Scott.

appear, for, as I said in my last letter, to whom is little Little Pedlington a stranger?

What, indeed, would the departed spirit of Simcox Rummins, F.S.A.,* have said, and what will the tuneful author of Pedlingtonia say to hear of one who dares to deny the existence of—

> "That all-delighting, glorious spot, which Pedlington we dub,
> Where brightly *shone* a Rummins, and where brightly *shines* a Jubb,
> Which, dazzlingly resplendent, "homologates" the fame,
> And claims the birth-giving of those, whom just above we name."†

To return to my purpose. When—to quote again the immortal lines of the author just named—

> "Science withdrew the ignorance which wrapped a magic art,
> A light on silver plates did play its photographic part."

The earliest steps taken for the advancement of this art were those devoted to the formation of a society. We had at that time several eminent artists residing in our locality, not native Pedlingtonians it is true, nor to be compared with our *Daubson.*

> "Who drew the all-but breathing grenadier;"

but, nevertheless, gentlemen who took a very active part in organizing the new society. One became its president, another its vice-president, and others members of its council.

The first meeting night brought a full attendance of members. And our Vice President, Sir Simon Sharpton, read a paper in which that worthy gentleman, while urging the importance of good photographs, nevertheles asserted, that, if anyone preferred bad to good photographs, they should be permitted to produce such.

Thereupon great commotion ensued. Mr. Sirocle, of scientific repute, rose with the air of a giant who could crush, and had a great mind to do it, and he scowled intensely, or smiled in pity, on the V.P. while he spoke at great length to the following effect:—"He and the author of that paper differed in toto, as widely as light from darkness:" after which many other members rose and scowled intensely, or smiled in pity, also asserting that they too "differed in toto as widely," &c. Then certain artists rose and they said, "That they differed in toto as widely," &c. from the last speakers (who singularly enough all professed to be more or less scientific), and so they ultimately, after many words and much wrangling, concluded by agreeing that henceforth and for ever, they were determined to "differ in toto as widely," &c. And so were formed our first party feelings, the artists separating themselves from the scientific men, and the latter from the former, and both resolving individually and collectively that while they would always support their own party, they would always denounce the other party, such being in their opinion the most generous and noble line of conduct they could pursue as earnest men of principle, and active members of a society established for the advancement of the art and science of photography.

Just about this time a presumptuous Londoner, who had come into our peaceful and beautiful little town, to claim some property left him by a deceased relative, rashly ventured to start a journal in opposition to our far-famed old established papers the "Little Pedlington Weekly Observer," and "The Little Pedlington Dictator," which he called "The Pedlingtonian Journal."‡ In this journal, after a description of the above meeting occurred the following insolent and insulting remarks.

"For the establishment of a good understanding it must be remembered by these gentlemen that photography is an art as well as a science, and that the progress of the same is as much dependent upon the representatives of the one as of the other element. Perfection in this art will therefore be the result of harmonious combination amongst themselves; but, if influenced by the selfish feelings of jealousy, or the petty desires of vanity, these representatives waste their time in contemptible bickerings and squabblings for personal prominence and power, or mere efforts for fruitless victories, the gradual downfall of the society and degradation of the art it is established to serve must be the inevitable result. We are sorry that in ushering our new society into existence these facts appear to have been overlooked, and we hope that the serviceable gifts of art and science will, by virtue of their common aim and end, be harmoniously united at its future meetings. We remember reading in an old number of the *Spectator* the following remarks, which we recommend the gentlemen concerned in the above discussion to peruse. 'We find that there is a sort of economy in providence, that one shall excel where another is defective, in order to make men useful to each other, and mix them in society. This man having this talent, and that man another, is as necessary in conversation, as one professing one trade, and another another, is beneficial in commerce. The happiest climate does not produce all things; and it was so ordered that one part of the earth should want the product of another, for uniting mankind in a general correspondence and good understanding.' Looking at photography in this light we must again express our earnest hope that its evident mission will not be set at nought by such feelings as were displayed after the reading of Sir Simon Sharpton's paper."

I beg pardon for inflicting so long, tedious, and absurd a quotation upon your readers, but isn't it folly to suppose that such men as Sirocle, and those forming his party, don't know everything, that mere artists—acknowledging as Sir Simon Sharpton did, that he was not a scientific man—should be able to teach *us scientific* men, who know all about cameras, and baths, and lenses, and how to produce pictures. If I can talk to you about the chemical elements, metallic and non-metallic; about mixture, combination, and chemical affinity; about bases, acids, salts, double decomposition, &c., and can moreover discourse about double or single concave and convex, meniscus and aplanatic lenses, &c., &c., &c. In short if I have had half-a-dozen lessons in geometry and optics, and have some practical acquaintance with photography, who shall presume to talk to me about art? or insinuate that there is anybody who can teach me anything?—I am, sir, yours most respectfully, Tripod Cameron.

West Street Lane, Little Pedlington, June 21, 1861.

* See "Little Pedlington," by J. Poole, Esq., published by Routledge, Farringdon-street.

† "The Bright Spots of Earth," a poem by J. Shakespeare Spriggins, Esq.

‡ The folly of the attempt soon appeared when this rash speculator dared to decline the services of Saphho Cripps, dared to ridicule Daubson's Grenadier, absolutely declined to treat with Jubb for his great Epic poem in 265 cantos, and insulted several respectable tradespeople who sent him small presents which he returned with sarcastic thanks.

GEOMETRICAL ILLUSTRATION OF THE HARMONIC RELATIONS OF LIGHT AND SOUND.

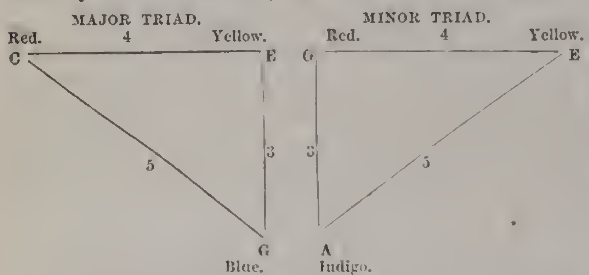
BY S. D. TILLMAN, A.M.*

In the course of my investigations concerning the relation of light and sound, and the analogy between the primary colours and the common chords, I have found a new method of representing the arrangement of musical intervals which possibly may lead to a clearer view of the relative position of colours. It is well known that in the tempered system of intonation common to all keyed instruments, only twelve different intervals are used within the octave, which consecutively form the chromatic scale. Theoretically, but not practically, these intervals are equal, and the scale of sounds may be represented in space by twelve grades of equal length, each of which measures what is erroneously called a semi-tone. In adapting the colours of the spectrum to this measurement of the septave, the lowest sound must correspond with the colour made by the lowest number of undulations and from that point each will follow in the natural order; that is, the red ray will coincide with the tonic, the orange with the supertonic, the yellow with the mediant, the green with the sub-dominant, the blue with the dominant, the indigo with the sub-mediant, and the violet with the sub-tonic.

In measuring the intervals forming the major common chord or Triad, we shall find from the tonic (red), to the

* Read at the American Photographical Society, June 10, 1861.

Mediant (yellow), four grades, or chromatic intervals; from the Mediant (yellow), to the Dominant (blue), three grades; and from the Dominant (blue), to the Octave tonic (red), five grades; making together the twelve chromatic intervals. In order to give distinctness to this measurement, I represented the length of the intervals of the triad by the sides of a triangle, and immediately discovered that one of the angles thereof must be a right-angle The intervals of the major common chord and the minor common chord are correctly measured to the eye in the following diagrams.



In the triad C is the tonic, and the intervals progressing upward are measured by 4, 3, and 5. In the minor triad A is the tonic, the upward or direct intervals being measured by 3, 4, and 5. In the one we have $4^2 + 3^2 = 5^2$, and in the other $3^2 + 4^2 = 5^2$. If these intervals in a true temperament are measured by the more minute divisions known as commas, 17, 14, and 22, will mark respectively a major third, a minor third, and a fourth, corresponding with 4, 3, and 5 of the tempered system. The sum of the squares of 14 and 17 is 485, and the square of 22 is 484. This variation of one comma in the result simply proves that the intervals of the octave cannot be precisely measured by true thirds, and it may be practically shown by the violin that twelve fifths taken consecutively upward will reach a sound exceeding in pitch that reached by seven octaves measured upward from the same fundamental.

For all practical purposes, the right-angled triangle whose sides are as 4, 3, and 5, may stand as an index of the intervals forming the major common chord, and likewise show the relation of the three primary colours; while the triangle having sides as 3, 4, and 5, will show the relation of the intervals of the minor common chord, and of a triad of colours in which the indigo or darkest ray is substituted for the blue; this relative arrangement producing up through the eye the same depressing effect that reaches up through the ear by the use of the minor mode.—*American Journal of Photography.*

IODIDE OF SILVER CRYSTALLIZING FROM NITRATE OF SILVER A CAUSE OF DEFECT IN NEGATIVES.

BY L. M. DORNBACH.

NITRATE of silver in solution dissolves iodide of silver in variable proportions corresponding to the degree of saturation, or strength of solution and the temperature at which the bath is saturated with the iodide. Hence, when a silver solution that is quite strong—say 40 grs. and upwards to the ounce—is charged with all the iodide of silver it can take up, and the temperature of the bath should afterwards fall several degrees, the excess of iodide of silver, corresponding to the difference of the two degrees of temperature, will crystallize out in the form of small tetrahedral and octahedral crystals, which adhere to the sides of the bath and also upon the plates introduced, which will then exhibit small holes after being fixed. This annoyance is more generally experienced during the winter season.

The remedy for the difficulty is, to filter the bath from the crystals of iodide of silver deposited, after which no more will be likely to form; or, after saturating the bath with the precipitated iodide and filtering it, add about one fluid ounce of the silver solution which had been set aside, and which does not contain any iodide of silver.—*Humphrey's Journal.*

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 24th July, 1861.

IT is probable that it would prove not an unprofitable task to take up the rejected agents in photography, and submit them anew to investigation. It would, doubtless be found that some among them have been rejected on insufficient grounds, or have fallen into disuse by the more prompt and temporary success of rival agents.

When glycerine was proposed as a preserving agent for collodion plates, we were sanguine that it would prove a useful adjunct, quite as good, in fact, as honey or raspberry syrup. Why it fell into abeyance we cannot divine. But it is just one of those things that is worth looking after, to see if it has not been unjustly slighted. M. Gaudin has laudably attempted to resuscitate it. Recently, you had his experience in adding it to the nitrate bath; he has now experimented by adding it to the collodion itself, and with results that must be regarded as curious and encouraging. He further proposes to try the effect of adding it to the developing agent.

The same experimentalist has also come to the conclusion that collodion, to be in good working condition, must be acid, or have free iodine present in it, otherwise veiled, or fogged pictures will be the rule rather than the exception. Thus it appears that collodion, nitrate bath, and developing agent, must each and all be in an acid condition. Mr. Gaudin's account of his experiments with acid collodion will be perused with interest.

It is rumoured that M. Niepce de Saint Victor, ardently pursuing his researches in heliochromy, has succeeded in producing colours in great brilliancy with a greater degree of permanency than has hitherto been obtained. The coloured images, it is said, will resist the action of strong sunlight for several hours. We know, from past experience, that a very little success goes a great way, when photography in natural colours is concerned, and if M. Niepce succeeds in attaining the promised result, it will be against hope. It is assumed that the pictures in natural colours will in every particular, be true to nature, with all the harmony of hues and tones, and with due gradations. A faint tinge of green in one place, of blue in another, and red in a third, although they may occur in spots representing tree, sky, and tiled roof, will hardly be accepted as a satisfactory solution of the great problem of photography in natural colours. And these results are the most that has been displayed at present.

Photography, it must be admitted, is a difficult art, although its manipulations are now tolerably sure and easy. It cannot surely be necessary to enter upon the much vexed question of photography as a fine art, for such it is admitted to be by all rational and reasonable minds. I do not despair of seeing the productions of those photographers who, by their works have proved themselves artists, fitly placed in the forthcoming Great Exhibition. But photography would suffer no harm, even if its products were mingled with mining and agricultural implements; our art would suffer no derogation, while the implements would be honoured by the association. I say, let the executive put the photographs where they will, so that they can be seen: they will be none the less photographs and works of art. Those who would reject photography from a place among the fine arts may justly be suspected of knowing nothing either of Art or of photography, and the profounder this ignorance, the greater the obtuseness and obstinacy.

Your executive should come and see how much better they manage these things in France. I believe the humblest artist would resent as ridiculous the question, "is photography a fine art?" if it were put to him. Like painting and sculpture, it is true, photography is, in some hands, a manufacture; but when its operations are directed by intelligence and refined taste, and evince a knowledge, in the person of the operator, of the principles of art, both in selection and rejection, then must the products have just and full claims to be regarded as works of art.

No person can walk through our present photographic Exhibition, and entertain any doubt of the title of photography to rank among the fine arts. If he has eyes to see, he will encounter pictures in which the profoundest knowledge of art is evident,—in the pose of the model, in the harmony of the tones, in the richness of the colouring (or rather of the *chiaroscuro*), and in the selection of the most favourable point of view. There are abundant photographs in which every particle of feeling for art is absent; but there are as many pictures and works of sculpture which exhibit the same deficiencies, and neither one nor the other should take rank among the products of artistic genius, but are strictly to be classed among manufactures. Those whose power of discrimination happens to be weak, admit *every* product of the pencil and the chisel—no matter how deficient in true artistic qualities—to be ranked as works of art, and in this lack of discrimination lies one of the greatest foes to true art.

A feeling is gaining ground among our most intelligent photographic artists, that the best results are to be obtained by pictures enlarged from very small negatives. Landscapes so produced avoid the difficulty arising from the varying foci of the different planes, while in single figures and groups, far more harmony, and an almost complete absence of distortion is secured, while the expression, which generally escapes from the model during a prolonged sitting, is almost certain to be secured in a negative of small dimensions requiring but an instant's exposure.

M. Gaudin has published a ready method of reducing silver from baths, &c., in a very pure state, from which nitrate can be re-formed. He states that of all the methods he has employed, it is much the most expeditious and the best. Previously, he reduced silver from its chloride by means of zinc and diluted sulphuric acid, then the salt of silver itself by zinc, after having acidified it with nitric acid. This latter method is very expeditious, but the reduced silver is always mixed with acetate of silver, which upon being dissolved in nitric acid, produces a magma of a brick-red colour, which dissolves with great difficulty in water, and makes very bad bath solutions. The silver reduced from the chloride is the best, but there always remains some chlorine not acted upon.

In reducing the chloride by the new method the nitrate of silver obtained from it is very pure, and the reduction is made with the greatest facility, when small quantities are operated upon, which is the only condition in which the process is applicable, and, therefore, especially useful to amateurs.

After having reduced and washed the chloride of silver obtained by adding hydrochloric acid to the ordinary silver baths, and dried this chloride upon a filter, it is placed in a hollow made of a piece of carbonized wood, and covered with ignited charcoal in a crucible, and a stream of air directed upon it from a bellows, so that the flame of the charcoal is directed upon the chloride; this soon melts; then, continuing the blowing, it is very quickly reduced to a button of metallic silver, entirely free from lead, which is almost the only metal that gives an insoluble chloride, like silver. The operation is completed when the chloride ceases to give off a white smoke.

PHOTOGRAPHY IN AUSTRIA.

Sir.—Observing that a portion of an absurd letter which appeared in the *Times*, has found its way to the Photographic News, and is calculated by implication, to give an erroneous impression of the treatment of photography in the Austrian dominions, I take the liberty of informing you that during a recent visit of some weeks to the Venetian kingdom, I never found any but the greatest courtesy—the only notice taken of my performances by the police, was to prevent people going in front of the camera! I have thought this might be acceptable to such of your readers who may visit the Queen of the Adriatic, than which few places afford such food to the photographer.

As the letter in the *Times* referred to treatment at the frontier, I may mention that when at Peschiera I requested the Austrian official to open my photographic box with care, he immediately closed it again, saying he would not risk doing any harm.—I remain your humble servant,

A Constant Reader.

July. 1861.

HYPO *versus* CYANIDE.

Sir,—I enclose for your inspection a stereoscopic plate, one half of which has been fixed with cyanide, the other with hyposulphite of soda. The plate was cut through with a diamond before exciting, and exposed in a bi-lens camera; it was then developed, and afterwards broken in two and fixed, as I have before stated, one half with cyanide, the other with hyposulphite.

The negatives were then placed side by side and printed on a piece of paper. The negative fixed with cyanide is rather whiter on the surface than that fixed with hypo; but there is not that difference in apparent intensity I had been led to expect. You will observe that the hypo negative retains its creaminess on both sides, while the other is creamy only on the side next the glass.

The prints, as you will see, give the effect of a slight difference in exposure in the negatives, the hypo negative seeming most done. The collodion used for this experiment was one containing a large proportion of bromide, and the bath contained an acetate.

I was somewhat surprised at not finding more apparent difference between the hypo and cyanide; but in the printing the result is decidedly in favour of the hypo fixing, the print being rounder and more delicate, with less tendency to harshness in the contrasts. In some instances I have found a more marked difference in the results, but always in the same direction. Please make any comment no these remarks you may think advisable, and oblige, yours, &c. J. C. Leake.

THE "HELIOGRAPHIC PRINTING" PATENTS.

Any means of repeating by lithographic impressions the beautiful half-tone and delicate light and shadow of a photoghraph is certainly much to be desired. The best attempts I have seen, however (and one or two were certainly very fine), have fallen very far short of the mark, and leave very much to be done in that direction yet.

All the attempts I have made have been so far deficient in delicacy, when looked at beside the photographic impressions of same subjects, that I abandoned each trial with a certain measure of disgust and began some other process which I thought would succeed better, in its turn to be discarded also, and have yet got no results fit to show publicly. I have tried all the methods specified by these patentees (and many others) and almost despair of getting rid of the *granular* appearance they all produce—which, though it *might* be tolerated on a very large picture (on perhaps a rustic subject), would never do for a small picture, or where very soft tints and distances are necessary.

It is a pity these gentlemen, instead of trying to help us on, either to something new, or to some other and better means of treating the old methods of accomplishing these desirable ends, entramelling progress by even patenting what is already known in that field of investigation.

After telling us that they do not "claim generally the use of bichromate of potash, &c.," they tell us what they "do claim," and, unfortunately, what they "do" claim is nearly all as well known to those practically acquainted with photolithography as what they do not "claim generally."

The 1st, 2nd, and 3rd claims as to the use of ordinary lithographic transfer paper, and the coating *it* with bichromate, &c., is no novelty; I have used every modification of transfer-paper, with gum tragacanth, isinglass, rice-flour paste, starch, &c., &c., long ago, and would not now think of using much less patenting them, as much better methods are well known, and I have no doubt every *lithographer* who has tried photo-lithography has begun the transferring of his impression from his own transfer-paper. "Hard surfaces free from granular texture," have also been used, if plate-glass, and copper, steel, brass, and zinc plates are to be considered such, and "dextrine," "gelatine," and "albumen," are certainly thoroughly known, as well as many other kindred substances that have been used for the same purpose long ago.

The 4th claim of mixing "pulverized mineral and earthy substances" with the compositions is no novelty either. I have tried silver sand, flour, emery, powdered charcoal, brick dust, and many others, which all produce (and naturally enough), but variations of the same granular and mealy effect.

The fifth claim, about the aqua-tint grounds, &c., transferred to the impressions has been, *in effect*, published by Fox Talbot in his "Engraving Processes," and similar means have been recommended by S. Pretsch for the galvanographic process, as well as ruled lines, dots, &c., and there is some *reason* in this case, as the most *delicate* aquatint shades will bite into and print from the plate, but will not transfer to the stone without either becoming gross and rough, or disappearing entirely. I have tried a great many methods for that purpose. I enclose a small piece of a ground I used which succeeded pretty well and could be made close and fine, or coarse and rough as desired; but ruled lines (done by the machine), and crossed various ways produced certainly the nearest approach to the thing of any.

The sixth point claimed as a novelty that of producing prints in colours is just about as old as lithography itself.

The seventh, and last item claimed, that of coating the picture (when done on metal), with "acid-resisting varnish" so as to bite away the metal and leave the picture intact and thus get a plate to print from, is by their method not worth claiming, seeing you can coat with etching ground and bite in the picture *without* the bichromate composition being between the varnish and the plate (as in their method) and so can bite deeper and with greater certainty. I have sawn off a small piece of a plate, which I send you, done in that way a considerable time ago, and have done it often. It needs considerable *depth* for surface printing.

The only thing really new, I think, in the specification is the coating the lithograph stone with a hardening surface of silex, &c., which must be necessary where the bichromate preparation is between the stone and the ink, but when it is best to put the picture on the stone itself, so that the greasy matter of which it is composed is in actual contact with it as in the usual printing method, the hardening is unnecessary.

Of course these gentlemen may, by the methods others fail at, be able to produce valuable results, and I should rejoice to see it, and be the first to laud these efforts even though at first they did not arrive at perfect success; all I object to is the claiming as their own property and invention means and appliances which have been known and used by others who are at work in the same field of investigation.

I enclose you one or two *line* subjects which I have done, and for which in our present state of advancement it seems best adapted. James Ramage.

OPTICS AND PHOTOGRAPHY.

Sir,—If your correspondent "A Photo-Student" (see page 331) is really ignorant about lenses, he will find it much easier to get popular information about the optics of an object glass for a telescope than about a portrait lens, and the first will help him not a little. Let him read such works as "Dick's Practical Astronomer" in default of higher food. Still I quite agree with him that we do want fuller information about our lenses and about every other subject. Your valued correspondent, Lake Price, gives diagrams in his work which are very useful; but in trying a lens I want to know "*how much*" to expect from it. For a given diameter and focal length what depth of focus in inches? What flatness of field in inches at a given distance? If Mr. Price had added definite details, one would have had something of a standard to go upon, but I may call a lens flat, and another may call the field round. I have not the opportunity of trying them by the dozen. Then, again, in what ratio to the focal length ought a good lens to work without a diaphragm? If I try a telescope, I go by certain ascertained rules, and soon pronounce an object glass or a speculum good or bad—the same with a microscope—but for a portrait lens I am not aware of any standard of judgment. Let your learned correspondents see to this, for the days of guess-work are fast fading away.

Birmingham, 24th July. J. Davis Burton.

Sir,—There is an article in your journal of the 12th inst., wherein I am attacked in such a manner that I think your readers will coincide with me in designating it a gross and unprovoked insult, and written with the intention of verifying the words of Shakespeare, "But he that taketh from me my good name, steals that which enricheth him not, but makes me poor indeed;" and that by an anonymous scribe too. Therefore I write this reply, not doubting but you will see "fair play" by inserting it in your next. Your writer having thrown down the gauntlet to me, I request you to give me his name: if you have it not, I call upon him to do so, that, in the contest he seems desirous of provoking, I and your readers may see the sort of antagonist with whom I have to do.

I certainly was somewhat astonished to see such a self-contradictory, confused trash inserted in any photographic journal, in which the writer has delineated his own likeness, and which, according to recent additions made to our knowledge of zoology looks very much like a "Gorilla," and in which he makes so free with other men's names (and reputations), without giving his own; the right epithet for such conduct comes at once to the tongue's end. I presume it must have got into the Photographic News by one of the youngsters in the office—either by design or accident—having picked it out of the waste-basket from among similar rubbish, where the editor throws such *stuff*—taken it to the type-setter, and thus I account for its insertion.

I now analyse the trash. In the first part, the writer states two or three times over that there is a disinclination to go into optics, to evade the subject. I believe him so far as he is concerned, or he would have had no need to come before the public *crying* for *simple* information, after having read valuable papers which *he* did not understand—in fact, almost all that has been written on the subject. His intellect must be the next link below the human, something like the zoological specimen above-mentioned. He does not want it learned and bewildering like Sutton's, neither must it be trashy like mine; then come Jupiter, come O ye optical gods, and give the exact *simple* information this stick-in-the-mud would-be optician is in search of. Man alive, put your shoulder to the wheel, apply yourself industriously, perseveringly to the study of optics, and *perhaps* you will get out of your miry incapability of understanding.

In another part of his precious confession, he advises me to go to school, and thinks the information will be singularly useful to me. What information—that which he gives or what I should get at school? If the latter—the former I will try to "make shift" without—I must take it as a compliment. He thinks I *am* capable of learning, which, I regret to remark, I cannot say as much of him; for he has read almost everything optical, and yet remains in a non-understanding slough of despondency.

Photo-Student wishes to know what a lens really is, and in what consists its real goodness. Reader, digest those two questions, and read the "bosh" of which the whole of his last paragraph is composed, and then remember *that he has read nearly all that has been written on the subject*, and draw your own inferences as to the effect his schooling had on this self-constituted judge on optics. He asserts that the chemical and mechanical portions of the science are pretty well understood; are they? If he understands them *well*, I am sure he would have been better employed in imparting that knowledge to others, than in exposing his want of *simple* information.

Photo becomes quite learned; at any rate he knows a little when he comes to speak about my papers. He can see that I know nothing—worse than nothing. My papers, in portions, are full of errors; in fact, from not knowing the A B C of optics, he has now become a judge, competent to pronounce the papers nonsense; yes, but they are composed of such nonsense that he, with his *affected* ignorance and real skill, whatever that may consist of, cannot controvert a single point in them. I here challenge him to prove (and surely he will not refuse it, after his bombastic, dogmatic condemnations) argumentatively or by experiment, a single error in the six papers now published, and leave every reader to judge for himself. All I desire is that every photographer examine the arguments and assertions I have made, and try the experiment stated in my papers, and if they do not find all I have stated correct, then I will admit that the notices of dissent by the editor of the "British Journal" are worth "paying attention to."

Mr. Editor, I believe you are right, when you say you suspect he has more general information about the whole subject than he confesses to possessing. If such is the case, what is his object in sending you the communication at all? Can you make anything out of it but an intention to attack me and depreciate my papers, in an indirect way, and that a very vile one; for if his ostensible motive (acquiring information) had been his real one, he had no occasion to drag my name forward, and make the insolent, unfounded, *unproved* assertions he has done.—I am, Sir, yours truly, J. Rothwell.

1, *Hulme Hall Lane, Newton Heath, Manchester, July* , 1861.

[As Mr. Rothwell feels himself aggrieved, we, as in duty bound, admit his reply, although we cannot but regret that so much of it consists in mere epithet. "Calling names," as children phrase it, really serves no purpose. The "Photo-Student," in confessing his want of optical information, and complaining of that already in existence, expresses his opinion of the labours of Mr. Rothwell in terms which it may be admitted that gentleman may have some right to complain; but we think he is entirely in error in conceiving that there is any special animus regarding himself. "Photo-Student's" complaint is a sweeping one, and seems to comprehend every one who has any optical knowledge, either for what they have done or what they have left undone.—Ed.]

Photographic Notes and Queries.

The Soidisant Gorilla.

Sir,—Having been a subscriber to the Photographic News from the commencement, and an occasional reader of all the other photographic periodicals, I was startled the other day by meeting with a letter in your Liverpool contemporary, headed "Photography by Machinery," and signed "The Gorilla," intimating in unmistakeable terms that a recent paragraph in your "Talk in the Studio" regarding the specification of Mr. C. F. Flounders of Liverpool, was a fabrication; stating in so many words, that you were either the victim of a hoax, or were wilfully hoaxing your readers.

Now, Sir, you will pardon me when I admit that I muttered to myself the old proverb, "Once bitten, twice shy," and resolved if I had been "sold" by the News once, I would not be "sold again;" for when one's reliance in an Editor's good faith is shaken, it is not, I fancy, of much use to waste time in continuing to read his paper. I resolved, however, to take the simple steps of satisfying myself, as it happens that I have considerable interest in such mechanical applications. I went, therefore, to the Patent Office, and having, with some hesitation, made the necessary inquiry, I received, instead of a curt negative, a specification containing eleven folio pages, "bristling with figures," and bewildering descriptions of intricate machinery, together with a broad-sheet of diagrams, in which "Charles Fontayne Flounders of Liverpool, Lancaster, "sets forth the nature of his invention for "duplicating photographic impressions, and also for certain machinery for the same."

Well, Sir, what are we to think of a journal, the conductor of which, neglecting to take the simple trouble of verifying a statement interesting to its readers, gives insertion to a letter denying the existence of Mr. Flounders altogether, declaring the whole affair a hoax, and at the same time gives a certain amount of editorial sanction to this letter by calling attention to it in the answers to correspondents?

"The Gorilla" truly states that the announcement of a photographic patent by a Liverpool man might have been expected to have appeared first in a Liverpool journal; but because it did not, does it mend the matter to add misstatement to neglect, and endeavour to deny a fact?

Where is the hoax, Sir? Not with you; for I have the specification before me. Has Mr. C. F. Flounders gone to the expense of not less than £50 for the sole purpose of hoaxing you? Or is it a hoax or something worse on the part of your contemporary?—Yours, &c., A London Photographer.

P.S.—I cannot forbear asking if the conductor of your contemporary had not at one time a great objection to the bad taste of what he termed "nominal designation," when referring to a brother editor, and may I ask your opinion of the singular taste or peculiar aptitude with which the correspondent in question writes himself down "The Gorilla?" L. P.

[The whole business displays a piece of "singular taste," upon which we have little disposition to comment, nor will our readers deem it necessary that we should do so. There is possibly more aptitude in the *nom de plume* assumed by the correspondent in question than you dream of. The editor of the journal had, and we believe has, an objection to the practice to which you refer, and, if we estimate him correctly, you must not charge him with complicity in such a silly business. There is "a power behind the throne greater than the throne itself."—Ed.]

Packing Dry Plates.

Sir,—I purpose taking a photographic tour of about three weeks: my plates are to be prepared by the Fothergill process: I should be glad to know whether I can safely pack them in a parcel with slips of *writing* paper between them; or whether I must increase the amount of my impediments with boxes which will also occupy considerably more space than a parcel.

Perhaps *blotting* paper would be better than paper such as this?

I should also like to be informed of the purpose of the addition of citric acid in the albumen, as recommended for the Fothergill process in the Photographic News Almanac.—I am, sir, yours, &c., Fothergillian.

Westminster, S.W., 22nd July, 1861.

[The neatest and most compact method of packing sensitive dry plates is that adopted by Dr. Hill Norris in the plates sent out by the Patent Dry Plate Company. A strip of cartridge paper is folded alternately, each way in folds about a quarter of an inch broad. The plates are packed in dozens with a fold of this paper between each plate at the end, the sensitive surfaces facing each other. The paper is really made to form the grooves of a plate box; and when a dozen plates are thus arranged, they are tied tight with a piece of string and packed securely. A great many plates are thus secured in small compass. Do not attempt to place any kind of paper in contact with the whole of the sensitive surface; but each negative as it is completed and varnished may be packed with paper next the surface. The addition of citric acid in the formula named, forms citrate of ammonia, and this tends to convert any trace of free nitrate into the citrate of silver, aiding keeping qualities and clean development.—Ed.]

Historical Parallel.

Sir,—May I venture to ask if there is not a very striking historical parallel to be found in the remarks of a certain photographer, as recently published in the Parent Society's journal, and the following as made by another eminent personage?

"*Dogberry*—Dost thou not suspect my place? dost thou not suspect my years? O that he were here to write me down —*an ass!* but, masters, remember that I am an ass; tho' it be not written down, yet forget not that I am an ass. * * * * O that I had been writ down—*an ass!*"—*Much Ado about Nothing*, Act 4, Scene 2.—Yours truly, A Photographer.

Talk in the Studio.

Photographic Micrometers.—Micrometers have been constructed by the aid of photography by Mr. Clarence Morfit of New York. He has thus succeeded in reducing a scale of ten inches divided into tenth parts of an inch to the length of half an inch. This method of reduction promises to be the most simple and economical hitherto devised.

Photographic Colouring.—Circumstances having induced Mr. Wall to dispose of his premises in Old Bond Street, he requests us to say that all future commissions should be sent to his private address, No. 11, The Terrace, Walworth Road.

Art Photographs.—We received from Messrs. Jackson, Brothers, of Jumbo, near Manchester, some further specimens of their choice photographs of rural life, in all of which the same careful attention to the composition of the picture, harmony of tones, and general chiaroscuro to which wer eferred a few weeks ago, is manifested. From subjects which are in themselves the most unpromising, the most effective pictures are produced. Here, for instance, is a "Rustic Porch," not formed of grotesquely twisted branches intertwined with jasmine, honeysuckle, or climbing roses. Not a vestige of foliage is present, but a whitewashed porch to a rough-brick cottage, with every line of the squarest. It is approached by some tumble-down steps, bounded by some broken wooden railings. The picture is taken in sunlight, but there is perfect drawing in the whitewashed porch, as well as in the deep shadows. The straight lines of the porch are broken on one side by the figure of a child, whose drapery also just serves to break the contrast from the white porch to the dark bricks of the house. A child's dress hung on a nail to dry at the other side of the porch, admirably serves a similar purpose. The open door, which would otherwise be a mass of black shadow in the midst of the white, displays a mother nursing just within, and beyond a child sitting; these lead the eye right into the deep shadow and give it perfect transparency. We cannot enter into detail of every picture, but may mention a "Dry Dock" as another admirable composition. We should recommend those of our readers interested in art photography, to procure some of these photographs: as, independent of their interest as pictures, they are extremely valuable as studies of how much may be done with little means, where a right appreciation of art-guidance is manifested. The published price, we believe two shillings, appears to us to be ridiculously low for whole-plate photographs of such quality.

Life-size Pictures.—We have recently seen some solar camera life-size pictures which have been touched in black and white chalk by Mr. A. H. Wall. The phrase "touched" appears in this case a very appropriate one, as the amount of chalk added was so slight as to be almost imperceptible. The result was, however, amazingly effective: from the crude and somewhat coarse appearance common to too many solar camera pictures, the transformation was complete, and a fine rich mezzotint effect produced, with quite sufficient delicacy for pictures of such a size, and intended to be viewed when hung, and not examined as miniatures.

To Correspondents.

Fixing Process writes as follows:—"Sir,—The proposal of 'Acetic Acid' is not bad. Jeremy Bentham suggested that a copy of his fallacies should be painted on a board in the House of Commons, and that when a member tumbled in his speech on one of them, he should be checked by the Speaker, simply exclaiming and pointing to 'No. 1' or 'No. 10,' as the case might be. So, if in our societies a member gets out of his depth and begins to struggle, if the President were to exclaim 'Gorilla,' the member might be saved from drowning himself, and taking the hint, would no doubt clutch at his seat, and become silent. How many would thus be preserved from the danger of getting into deep water."

G. G.—We think it probable that under the circumstances you name, a coating of gallic acid may add to their certainty. We are glad to learn that you succeeded with your camera.

Dr. Hanlon.—The glass shall be duly examined. We observe it is a flashed glass, which is not best in principle.

Investigator.—We have repeatedly given the methods of separating silver from waste solutions; you will find the subject treated at length in page 50 of the present volume. Unless you use very large quantities of gold in toning, it will be scarcely worth the trouble of attempting to recover it. Any gold remaining in the toning bath may be precipitated by means of photosulphate of iron; but it is best to use no more gold solution at one time than you are going to exhaust, as nearly as possible, in toning.

H. W. Ball.—The tendency in the film to leave the glass, may be produced by several causes. An acid nitrate bath will often cause it, as will also a very contractile collodion. Developing in a dish instead of pouring on the developer will also tend to the same result, especially if the former causes are present. To avoid it, without altering your bath, be careful to allow the film to set well before immersing the plate in the bath; be certain that your plates are clean, and let the collodion run well up to all the edges of the plate; you may also slightly roughen the edges. If these means fail, try a fresh sample of collodion, or add some fresh nitrate solution to your bath.

Tit tat to.—We are not quite certain from your description of the nature of the defect of which you complain. If, as you state, there is a want of sharpness in some parts of the print which are quite sharp in the negative, it can only arise from a want of perfect contact in the pressure-frame between the sensitive paper and the negative. If the contact be not perfect throughout, the print will not be sharp in the places where the pressure is imperfect. Probably the addition of another piece of soft elastic felt behind the sensitive paper will remedy the defect. If this be not the cause, you must send us a specimen, and we will further help you.

Y. W.—You have done right in making your gold into one solution, and your phosphate of soda into another, to be kept separate, and mixed when required. We cannot tell you whether the quantities of each solution you name are right, without knowing the strength of the solutions. If we remember correctly, you some weeks ago referred to the strength of the solutions; but we cannot remember the figures mentioned in all our correspondence. You may, however, mix the smallest possible quantity, by adhering to the proportions named in the formula. The colour of the background in your pictures will be regulated by the colour of the screen you use for a background. If you require a dark background paint the screen a dark grey.

J. S. L. P.—Omit the muriatic acid from your formula. Let your pictures be slightly under-exposed, and well developed in the first instance, and you will have less tendency to blueness in the further operations. The solution sold by the house of whom you purchase the varnish does not, we believe, produce blueness.

H. B. Y.—You may use your portrait lens for landscape purposes, if you place a diaphragm between the lenses; one of about a quarter of an inch diameter will be small enough for a quarter-plate lens. If you use the lens in this manner the same camera will do. Or you may use the front lens alone, reversed, if your fittings permit of the arrangement. In that case you would require a camera to extend more, and the lens would cover a rather larger plate. 2. Precipitate your old silver baths with common salt, and either take the chloride thus formed to a refiner, or reduce it to the metallic state in a crucible with strong heat, adding twice its weight of a mixture of carbonates of potash and soda. 3. The only method of effectually screening a sitter from the sun in a glass house, is by a series of blinds inside, any of which can be drawn at pleasure.

An Amateur Photographer.—You may use the oxide of silver for the purpose without necessarily having it freshly precipitated. Shake a little up in a small quantity of water in which it will be held in mechanical suspension, and add a few drops to the bath, which must then be well agitated. This will neutralise all the free acid; then sun the bath and finally filter and acidify. The oxide of silver is prepared by adding caustic potash to a solution of nitrate of silver, a little at a time, until the whole of the silver is thrown down as an olive brown powder which is the oxide; after well washing, it is ready for use.

N. H. W.—The general plan of your glass house is good. If you can afford two or three feet more in height, so as to secure a height of 13 or 14 feet, it will be an advantage. Presuming that your sitter will be placed at the end where there is six feet of wood overhead, we should recommend you, if possible, to have a little more glass at one side of the house, and instead of 10 feet of wood, have only 6 feet at one side. This will often be an advantage in illuminating the lower part of the figure in carte de visite and standing portraits. For the rest the plan is very good. We should prefer to use the white sheet glass to blue. The fluted glass is the very best thing for the sides. Regarding mounting your lenses for a stereoscope, it does sometimes happen that a facility in varying the distance is valuable, but about 2½ in. or 2¾ in. from centre to centre, suits most persons. It will be useful to have an adjusting rack to alter the focus. In placing a diaphragm between lenses, the position is determined by the respective focal lengths of the front and back lens. Thus if the focus of the front lens be 6 in., and that of the back lens, 12 in., the stop should be placed about one-third of the total distance between the lenses behind the front lens.

J. C. Barnard.—It entirely depends upon how much you already know, and how much you need to learn. If you call upon us next Thursday afternoon we will endeavour to aid you.

R. Keene.—We will endeavour to ascertain for you by next week.

R. C. R. B. J., India.—Many of your queries are answered in former numbers which will by this time have reached you. The redness of the image on first developing, and the loss of density in fixing, seem to indicate the use of an old decomposing collodion. The loss of density in fixing sometimes takes place from the collodion being over-iodized. Fixing with hypo would tend to prevent such an effect. If tripoli and dilute nitric acid do not remove the spots on your glasses, reject them at once. Yellow negatives are produced by intensifying weak negatives, first with bichloride of mercury, and then with a weak solution of iodide of potassium. The possession of such a process is a valuable adjunct, but we do not counsel its general use. The practice of adding silver to the developer from the bath is not a good one, as that is saturated with iodide of silver &c., and will aid in causing stains and pinholes. It is better to keep a weak solution for that purpose only. Carefully avoiding dust and muddy solutions will generally prevent pinholes. All the causes you name will cause the spots, and should all be avoided. Your prints indicate the necessity of a stronger silver bath, much deeper printing, and fixing in new hypo. The negatives might be more intense with advantage. Read the articles on "Photographic Chemicals" we are now publishing. We cannot tell you where to procure good albumenized paper. Unless you are skilled in the use of tools, we fear you will scarcely succeed in making either a binocular camera or carte de visite camera, and we cannot here give you a description of the best method of going about it. The best lenses for carte de visite portraits are those made expressly for the purpose. Quarter-plate lenses may be used for sitting figures, but for the standing figures a half plate lens should be used, unless you have a lens made for the purpose. The best dry process for India will be, we apprehend, the collodio-albumen.

A. R. W.—We do not at present know of any one who is in want of such a camera stand.

Pieric.—You will find particulars as to price, &c., of the spectroscope on our first page of advertisements. We are obliged by your complementary remarks. We shall be glad to receive a description of your tent

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 152.—*August* 2, 1861.

INSTANTANEOUS PHOTOGRAPHS OF LONDON.

The term instantaneous photography is too often spoken of as if it were an absolute thing without any relation to time, place, or circumstance. Thus we hear of "instantaneous processes," "instantaneous collodion," "instantaneous dry plates," &c., without any reference to the other conditions necessary to instantaneity. What constitutes an instantaneous picture is not absolutely defined; in some instances an exposure of one second would be held to be instantaneous, and in others the tenth part of a second only would be required to produce a similar effect. In taking objects in motion, if the proofs are sharp and crisp without any blurring of the moving figure, the picture is held to be instantaneous. The rate of motion of the object, its direction across the field of vision, and the distance from the camera, are rarely considered, neither are the amount of actinism present nor the luminosity of the objects to be taken. If an instantaneous process were an absolute thing, then an express train, passing at the rate of fifty miles an hour, might unquestionably be photographed successfully, a feat which has not yet, we believe, been accomplished. The train passes over a space of about eight feet in the tenth part of a second, our readers may judge, therefore, the rapidity of the process necessary for securing a sharp image of an express train. Nevertheless, we have seen steamers at sea and clipper yachts before a smart breeze with all canvas spread, cutting the waters, perhaps, at a speed of twelve knots, or upwards, an hour, in which every line of cordage has been secured as sharp as if traced with a needle, waves with every crest of foam distinct, and flying clouds, without a blur. We were recently at the sea-side in company with Mr. Samuel Fry, who, in securing instantaneous marine effects, frequently found that the utmost possible rapidity of exposure, with an aperture of less than three-eighths of an inch, whilst giving perfectly instantaneous effects, in some cases produced over-exposure, such was the sensitiveness of the chemicals, the amount of actinism present, the luminosity of the objects, and the perfection of the lens. We may add, as a fact somewhat startling, that on one occasion that we—Mr. Hughes, Mr. Fry, and ourselves were present—secured fine effects of water, cliff, and sunset clouds at nearly nine o'clock on a July evening, with an exposure of ten seconds.

Instantaneous effects, in a city, present a new class of difficulties. Whilst the rate of motion is less rapid, it is more confused and varied; the objects are less luminous and the light is less actinic. Messrs. Ferrier and Soulier discovered this fact in producing their street scenes in Paris. If this were manifest in Paris, what must it be in London? The constancy and energy of the stream of moving figures, pedestrian, equestrian, and vehicular, and above all, the smoky, misty, non-actinic atmospheric conditions are well calculated to baffle the most ardent photographer.

Under these circumstances it is not surprizing that so few instantaneous views of London exist. We have recently received from Messrs. Dages and Harman, of Peckham, a score of specimens, of by far the best street scenes of London which have come under our notice. With a courage which is most praiseworthy, they have not shrunk from selecting many scenes presenting the greatest difficulties, where it has happened that they have at the same time possessed the most interest. Amongst these we may mention London Bridge Railway Terminus, with its crowds of cabs, omnibuses, and foot-passengers, London Bridge itself, similarly crowded, and the clock tower on the Surrey side. Charing-cross, the Strand, Fleet-street, Regent's-quadrant, and others, all present a similar scene of activity and bustle. In some of these it is quite easy to count upwards of fifty boldly-defined foreground figures, without mentioning those in the distance. There are also some very interesting river scenes on the Thames, with shipping and steamboats in full motion, &c.

It would be too much to say of these that they were all first-rate specimens of photography; but they are very good under the circumstances. The chief fault which strikes us—and we mention it because we feel assured that these artists having done so much are able to profit by the hint—appears to have arisen from some over-anxiety to obtain intensity. If we judge correctly, the negatives have been taken by some process requiring subsequent intensifying—probably by means of iodine, pyrogallic acid, and silver—and this has been carried slightly too far. The tendency in rapid processes is to the production of what Mr. Hughes has happily phrased a "phantom image." A negative with all the detail there, but so faint, so filmy, so transparent as to be little more than a phantom. To intensify such images at all, so as to secure printing qualities, requires some skill, and there is a great temptation to go too far, and so produce chalkiness. In these prints the distances, which at best in London are generally misty enough, appear obscured a little more than even the smoky atmosphere demands, by too long continued development or intensifying; the same process at the same time producing another defect—the white sky. But these drawbacks are not present in all, many of the pictures being surprisingly good photographs of such scenes.

The instantaneity is in many cases perfect. Here are omnibus horses with uplifted legs without a blur, and foot-passengers in every stage of action perfectly defined. Some few of the figures are not quite crisp and sharp, but this is chiefly where they have been defined with the extreme edge of the lens, rather than from want of rapidity in the exposure. Altogether they are very interesting, and, as we have said, the best instantaneous street views of London we have seen.

There is another hint we would throw out to these artists and others of our readers whom it may concern. The mounts of all photographs, and of stereographs in particular, should never be of a positive colour. The bright yellow of these mounts mars much of the effect. A warm grey, drab, or stone colour, in all cases as neutral and unobtrusive as possible, should be chosen, to secure the best effect.

THE FRENCH PHOTOGRAPHIC SOCIETY AND THE EXHIBITION OF 1862.

Some curious misapprehension seems to have existed amongst the members of the French Photographic Society when discussing the question concerning the proposed classification of photography in the forthcoming International Exhibition, to which their attention was called by the secretary of the London Society. Interpreting, apparently, Professor Playfair's letters in an authoritative sense, and regarding his strongly-expressed conviction that photography *must* be placed in its proper position, they are puzzled by the recommendations of Dr. Diamond's letter, which advise entire abstinence in contributing; and, as may be seen in the letter of our Paris correspondent, some of them are inclined to attribute sinister motives, and allow exploded notions of the supposed bad faith of "perfidious Albion," to take possession of their minds. The letter addressed, however, by M. Lauleric, the secretary of the society, to Dr. Diamond which we subjoin, is much to the purpose.

The letter is addressed in the name of the committee of the French Photographic Society, to the secretary of the London Photographic Society, and is as follows:—

"Sir,—I have the honour to inform you that the committee of administration and the general assembly have each met in succession to deliberate upon the grave communication which you have addressed to us in the name of the Photographic Society of London, on the subject of the forthcoming universal exhibition.

"The French Photographic Society is as much surprised as the London Society at the error committed in the programme of the Exhibition with respect to the classification of photography.

"It would only be necessary to visit one of our exhibitions to become convinced that photographs, at least such as have been produced with artistic feeling, are not mere mechanical products. For two artists, with the same apparatus, employed in the same conditions, will render the same portrait or the same view, not only in very different manners, but according to their individual feeling.

"Moreover, Dr. Playfair has himself demonstrated the error of classification in his letter, and with him, we do not doubt that the Royal Commission, if it can alter its arrangements, will be none the less disposed to practically rectify its theoretical error as far as possible.

"The French Photographic Society has doubtless the right and the duty to protest, with you, against the philosophical consequences of the error committed, since all its efforts, like your own, have tended to elevate photography to the dignity of an art; but, in participating the just indignation of the London Society, it cannot adopt the same conclusions.

"In the first place, our positions are not identical. You, as English exhibitors, can act directly upon the Royal Commission; but strangers, invited *as guests* to take part in the Exhibition, if they enjoy the undoubted right of not accepting the invitation, have no right to object to the conditions imposed. The Imperial Commission alone, doubtless, has an official character sufficient to state the observations of the French Exhibitors; and I must add that we have already received assurance of the liberal intentions of the Royal Commission with regard to photography.

"Furthermore, the General Assembly has unanimously recognised that in any case, even if the Royal Commission should consider itself unable to repair, as much as possible, the error committed (and we are well convinced of the contrary), *abstaining* will be the very worst mode of protesting. This abstaining would, in fact, have the effect of excluding true artists, whose works are the pride and honour of photography, and leave their place to be occupied by mechanics, whose detestable productions would, in the eyes of the public, fully justify the error of classification we deplore. We think, therefore, that so far from recommending the abstaining from exhibiting, Photographic societies should make a most pressing appeal to artists' worthy of the name, and be very severe in their selection of the works presented for exhibition. This exhibition, although in the midst of an Universal Exhibition, will undoubtedly, both by its interest and importance, be the most certain, useful, and worthy protest that can be made.

"The French Photographic Society, always animated with a vivid and sincere desire to maintain the happy union existing between itself and the Photographic Society of London; hoping that the latter, appreciating the conditions above stated, will neglect nothing to obtain in the execution the realization of the liberal intentions of the Royal Commission, the assurance of which has been given to us.

"On Friday next, the 19th inst., we shall have another general meeting, which will be the last before the vacation. The committee meet on Monday next. We have to request you to forward the communication we hope, sir, to receive from you, in time to arrive here on Monday, if possible, or at least before Friday."

Once more we take the opportunity of pressing upon the council of our society the importance of making the best of the offer of the Commissioners, and appointing a committee of good men to co-operate in securing justice to photography and photographers. That photographers, both at home and abroad, will exhibit, it is quite certain; the recommendation of the council to abstain, may impoverish the representation of the art, but cannot prevent it; whilst their co-operation and countenance may improve and elevate it. Surely it is better in some measure to guide, even if they cannot entirely control the issue. As the French secretary remarks, "abstaining will be the very worst mode of protesting." Those only might be expected to abstain whose artist's pride, or self-respect, was wounded; and theirs are the works, which in many instances, would most adorn and elevate Photography, whilst the absolute mechanics of the art would appear as its sole representatives, and justify, by their productions, the decisions of the Commissioners. Let it be rather the aim of photographers to prove, by the high character of their contributions, how blind was the judgment that placed them, in the first instance, in the same category as the hewers of wood and spinners of flax.

PHOTOGRAPHIC PATHOLOGY.

In another column will be found a letter from our esteemed correspondent, Mr. Francis J. Eliot, explaining some slight confusion of terminology which occured in a recent communication to our pages on "The Measles: its Diagnosis and Cure." As a contemporary, in an editorial notice, called attention to this a day or two ago, we think it right to state that Mr. Eliot's explanatory letter was forwarded for publication upwards of a week ago, but we were unable, for lack of space, to insert it in our last issue.

The suggestion of the term "measles," as designating a certain disease to which photographic prints are liable, was due to Mr. Hughes, and was undoubtedly intended to indicate the yellowish-brown spots arising from imperfect fixation. The mottled meally effect so common of late in albumenized prints, although certainly a cutaneous disease, is of an entirely different character, and proceeds from different causes. We commend Mr. Eliot's letter to the attention of our readers.

PHOTOGRAPHIC EXHIBITION AT MARSEILLES.

We have received from M. Vidal, secretary to the Photographic Society of Marseilles, a letter and prospectus of their intended Exhibition, to which he requests us to give publicity amongst English photographers. No effort appears to be spared in making this first Photographic Exhibition in the South of France as perfect and interesting as possible, both in photographs and photographic apparatus; in regard to the latter of which, the uses and modes of working, we are informed will be demonstrated to visitors. The opening is fixed for the first of September, and specimens and apparatus intended for exhibition will be received until the fifteenth of August. We subjoin an abstract of the principal regulations:—

1st.—The day for the opening of this Exhibition is fixed for the 1st of September, and it will continue open for a month.

2nd.—All communications and specimens are to be addressed, carriage free, to M. L. Vidal, secretary to the Society, until the 15th of August at the latest.

3rd.—They must be accompanied by a notice detailing the number of objects sent, and signed by the exhibitor.

4th.—The specimens exhibited must, if not mounted in an album, be enclosed under glass.

To avoid the expense and difficulties of transport, exhibitors who have not agents in Marseilles may have the privilege of addressing their proofs on paper to the secretary of the Society, who will take care that the proofs be put under glass, at the cost of the expositors, as economically as possible. In this case the communications should be forwarded not later than the 10th of August.

5th.—All proofs coloured, and all those which have been retouched so as to modify, in any essential degree, the photograph will not be admitted to the Exhibition.

6th.—All negatives on glass or on paper, on metallic plates, on stone or on wood, of which proofs are forwarded, will be received and exhibited with all necessary precautions, the same care shall be given to negatives sent to illustrate the apparatus, by which they have been obtained.

7th.—Exhibitors must inscribe their name on each proof or on the frame containing several proofs; they may also add their address, but they are requested to avoid further inscriptions.

8th.—The exhibitors of apparatus are invited to forward also their price lists, prospectuses, &c.

9th.—The subject of each picture and a summary of the process employed in producing the negative, whether wet or dry collodion, albumen, wax paper, &c., must in all cases be stated. All other information on the mode of operating will be valued.

10th.—The prices must not be indicated, neither on the proofs nor frames, nor on the apparatus exhibited.

11th.—The committee of management intend to buy a certain number of proofs for a lottery which will take place at the end of the Exhibition. The expositors, who intend to dispose of their proofs, are requested to mention the prices in their letter of advice to the secretary, who will communicate this information to the committee of management, and to the public. The same recommendation is made to the exhibitors of apparatus.

12th.—Specimens or apparatus exhibited cannot be withdrawn before the closing of the Exhibition.

13th.—The Photographic Society of Marseilles will have pleasure in receiving for a place in their archives all specimens which may be interesting as works of art, or as illustrating processes which contributors may be willing to place at their disposal.

14th.—All works intended for exhibition will be submitted to a jury of admission, selected from amongst the active members of the Society.

15th.—All objects exhibited will be returned at the expense of the expositors, within 15 days of the closing of the Exhibition. All letters to be addressed to the Secretary, No. 2, Rue Mazagran, Marseilles.

PHOTOGRAPHY IN THE UNITED STATES.

There are few things more interesting to ourselves than the glimpses we obtain from time to time of the progress of photography amongst our American brethren of the camera. Possibly pleasant personal recollections of some pleasant months' rambling about the States increase this interest. It is true that their journals are often very largely made up from the English photographic periodicals; but this is easily explained by the fact that there is a comparatively small amateur photographic public in America to communicate their experiences. There are few photographic societies and meetings to discuss things old and new appertaining to the art, and the conductors of the American photographic journals, therefore, wisely avail themselves of the interchange of ideas which is chronicled in this country. Their selections from our own pages and those of our contemporaries are frequently judicious, and generally acknowledged. We, in our turn, are enabled occasionally to give our readers the benefit of valuable practical papers from their pages. It must be acknowledged that at times their ideas are rather startling, and that they "leave the world behind" and "lose the beaten track" when they talk of producing twelve thousand prints an hour from one negative, and take bird's-eye views from balloons; use a mixture of "corrosive sublimate, tartaric acid, sal soda, and hydrochloric acid" instead of gold for toning, and "hard cyder and rusty nails" for developing. We now propose to make one or two extracts which will give our readers some idea of the collossal character which "Yankee notions" sometimes assume in connection with the commercial aspects of the art.

Mr. Fredricks, one of the principal photographers in New York, from whose atelier we have seen some magnificent portraits, and whose name may be remembered by our readers as the defendant in the long litigated bromide patents—of the termination of which by the way there has been no information—has recently opened an establishment for portraiture in Broadway on a scale which argues well for the state of the profession, despite the secession war; and will rather startle photographers in this country. *Humphrey's Journal* thus describes its dimensions :—

"The building is five stories high, 25 feet by 100 deep. The first story, front on Broadway, is a single arch, 30 feet high, covering a wide and very handsome vestibule, which opens immediately on the street, no intervention of doors separating it from the thoroughfare. This porch or vestibule presents in itself a fine collection of pictures, the sides being completely covered with elegantly-framed and finely-finished photographs of well-known local and other celebrities. The main gallery, or principal exhibition room, is on the street level, and is 20 feet high, 25 feet wide, and 100 feet deep; from this a wide staircase leads up to the second story, where are located the Ladies' Parlours and Toilette Rooms, which are fitted with every appliance desirable in such apartments.

"From the front of the principal parlour, which is fronted by a single large bay window, visitors can enjoy one of the finest views of the ever-varying panorama of Broadway that is to be found anywhere in the whole city. On the third floor is the principal operating-room, 50 feet by 25, its distinguishing feature being a hugh skylight, built in the form of an arch. This peculiar shape gives an opportunity for securing a strong light from any desired aspect, so that the weather is not permitted to make any difference in the excellence of the pictures. On this floor are also the rooms of the various artists in water colours and oil, whose labours are constantly in requisition in perfecting the highest works of photographic art.

"The fourth story is devoted to the Daguerreotype process. The fifth floor is reserved for printing. Mr. Fredricks employs thirty persons in the Broadway establishment, and so complete are the mechanical and artistic arrangements, that he estimates his facilities equal to the production of 180 negatives in a day.

"Every variety of photograph and Daguerreotype is made by Mr. Fredricks, the scale of prices running from one dollar, asked for a miniature plain photograph, to 600 dollars,* the regal price demanded for an imperial, life-size, full-length photographic portrait, finished in oil-colours by a first-class artist."

The *American Journal of Photography* describes the same building, and speaks thus of the vestibule :—

"The doorway is gracefully built as an arch, the keystone of which is nearly thirty feet from the pavement, and forms the entrance of a vestibule of the same height and width, and about twenty-five feet deep. The vestibule is ornamented and furnished in the most artistic and useful style. Its most striking features are a gallery for promenade, resting place, or sight-seeing on Broadway, and a large chandelier at the ceiling provided with mirrors which reflect the light down to every part of the whole space. The vestibule opens into the grand exhibition room, where the largest collection of photographs ever made greets the eye. The hanging of the pictures, and the management of the light (two rows of gas jets the whole length of the ceiling), forcibly remind one of the exhibitions of the old Art Union."

It is quite clear from the enterprize Mr. Fredricks exhibits that he does not regard the palmy days of photography as past, as we have heard more than one professional photographer in this country intimate.

We give another illustration pointing in the same direction, and at once showing the extensive notions of brother Jonathan and the extensive demands which create them. A recent number of the *American Journal of Photography* contained a small photographic portrait of Col. Ellsworth, on albumenized paper, about half an inch square. It appeared to be a reproduction either from an engraving or a photograph which had been touched up by the artist. It was accompanied by a paragraph to this effect :—"We present a sample of a photograph on albumenized paper, which may be printed by a single person at the rate of *fifty-thousand an hour*. Our guessing friends will please find out

* One dollar is 4s. 2d., and 600 equal to £125.

how such an astonishing feat can be performed; it is a fair problem and there is no trick about it." The last-issued number of the same journal gives a variety of solutions of the problem, from which we give some extracts. Mr. Simon Wing, of Waterfield, Maine, says:—

"My machine (patented) has four ¼-tubes,* and carries a plate 12×15 inches. Now we can use about 11×14 inches of said plate, and have a half inch all around it, to handle it by. Now these little prints being ½ inch square, we can get on to our plate of 11×14, 616 negatives, and by making four at a pop or more, and moving once in two seconds, it gives us one negative in one-half second, so we have our negatives in about five minutes; now we will run about ten plates through the machine, which will be enough for one to tend. Now one man can print one print from each in about two minutes, which will make thirty in an hour; so if we multiply thirty by the ten plates, making 300, and then multiplying 616 by 300, we shall have 184,000, which is more than three times what we are asked for, so we will tell how it is done and no one need guess again.

"First, we use four tubes, each tube being set in front of a quarter of the 11×14 plate, and four square ½ inch apertures through a plain board are placed between the tubes and the plate, so as to expose only enough of the plate to make four impressions, one for each tube; now move the plate one half inch either way and expose again, and so on till the plate is all covered.

"Our machines are simple and cheap considering their advantages over all other machines for the purpose, as we can use the same machine for every kind of work for which a camera is used, copying, stereoscoping, ambrotyping, &c., and using the common size plates; so the operator has not to buy a new bath, printing boards, &c., &c. The small size will make eighty little pictures on ¼ size plate, one half inch square like Colonel Ellsworth's, or the entire plate can be exposed at once and make a ½ size Daguerreotype, or ambrotype, or negative, or take either of the smaller-size plates and multiply on them, so the multitude can be accommodated with few or many, and melainotype plates, or niello paper can be used to great advantage by those who do not make photographs, and are more profitable to the operator and pleasing to the customer."

Another correspondent writes from Boston to the following effect:—

"I do not think it requires a very high order of guessing ability to determine how such photographs as that of Colonel Ellsworth may be readily and rapidly produced. I would think it strange if our skilful photographers generally would refuse a profitable order for work of that kind, from lack of inventive talent to execute it.

"It seems to me evident that the problem resolves itself into the various ways of multiplying a single image on the glass for the compound negative. One image only on a single glass cannot be made to yield 50,000 images in an hour, at least in the present state of our art; Fontayne's machine is *said* to have been worked at the rate of 12,000 in an hour, but has not produced anything of first-class photography.

"Now I would suggest that the compound negative may be produced by using a multiplying glass directly in front or behind the lens of the camera. Or the image may be multiplied by means of a multiplying mirror. In this way the compound negative would be made directly from the object, giving as many images as there are faces on the multiplying glass.

"I seriously hint that this idea is worth putting into pracpractice, and especially for card pictures. There can be no serious difficulty in making a multiplying glass of four or six faces of proper angles, and achromatised, if necessary, which would give at one sitting four or six figures, card size, with a single quarter tube. Of course, the time will be increased as much as the light is divided."

And finally Jonathan Slick writes from somewhere in Connecticutt:—

"Mr. Eddytur.—As I was sleepin' the other night very soundly except for the skeeters I heerd a great sound, like a fife, that made me start up on eend and think a biler had bust. But Polly Slick (that's my wife) had been awake, and was not at all afeerd I asked her if anything had broke loos', and she sed, 'it was only that tarnal crazy critter Jonathan.' (Jonathan is our youngest offspring.) 'Ever sens he's took to ambertipes and foetograffy, he acts like a darned fool. He's all the time talkin' about assids and oxhides and all kinds of pisen, and he gets his hands as black as an injen, and he's spilin' everything in the house with his baths and sensitizin licker. It's too bad and you must put a stop to it or there wunt be anythiug fit to be seen. Now he is cantankeratin in the night, and disturbin' all the nabers with his screechin. What do you spose he means by hollerin out "I kin dew it, I kin dew it"?' Was that what he sed, sez I, wakin up agin? You see, Mr. Eddytur, my wife's sientific edication was never anything to brag on, and she had never read about them sellybrated wurds of Arkimeedis, or she wud a none that our boy had diskivered something.

"Next mornin' Jonathan kep pritty scarce from his mother, and went a tinkerin in his room over the woodshed, which he calls his labritory.

"When he cum to dinner, he brung a basin heepin full of little picters of his mother and of the present riter. 'Goodness grashus! what on airth!' sez my wife. But she was kinder pleezed, and she didn't say a wurd about disturbin' fokes in the night.

"After dinner we all went out into the labritory and Jonathan show'd all how he did it. Up agin the wall he stuck about 2 duzzen hull size foetograffs of his parents; then he pinted his kamery and took 'em more'n twenty times. He said he was projucin negitives with about 500 figgers in each. Well, pretty soon we had the foetograffs on a sheet of paper.

"Now, of course, you know the little detales and prosesses, and I have rote enuff to show the natur of my boy's diskivery.

"Jonathan calkilates he kin make about 500,000 foetograffs in an hour if he was put tew it.—Respectfully for Sience,

Jonathan Slick.

"P.S.—The next time Jonathan goes down tu York with the slupe he will call on yure offis."

Our readers may possibly gain some glimpses of light from the "gas," which accompanies brother Jonathan's "guesses."

* The term "tube" is used for a lens.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Hydrobromic Acid.—This acid is of similar composition to the one last described, and is of considerable use in photography. The popular way of preparing hydrobromic acid, by adding bromine to alcohol, is a most imperfect and unsatisfactory mode, as an addition to the hydrobromic acid. there is produced a considerable quantity of bromal, together with aldehyd, and acetic acid. Bromal is a colourless, oily-looking fluid, of a peculiar irritating odour, producing a flow of tears. It is considerably volaitle, and for several reasons should be kept out of photographic preparations.

The ordinary way of preparing hydrobromic acid in the pure state is to distil a mixture of water, bromine, and phosphorus. The operation requires conducting with considerable care, as the reaction between the phosphorus and bromine is attended with such violence, that explosions frequently occur. The safest plan is to keep the retort cool with ice, and having put in the water and phosphorus, to add very gradually, through a funnel-tube, the bromine. When the portion first added is decolourized, a further addition may be made, and so on until the whole quantities have been mixed together, when the liquid may be distilled. In this process 12·5 parts of bromine are taken to one part of phosphorus. The liquid which distils over, if colourless, is pure aqueous hydrobromic acid, but if it be coloured it contains bromine, which may be removed by agitation with mercury, and redistilling. It would be a great improvement on this process, if amorphous, instead of ordinary phosphorus were employed. This red variety of phosphorus, which is now become an article of commerce, acts in the same manner as the ordinary kind. but its reactions are less intense. Even when this is used the bromine must only be added gradually, as the reaction is very energetic. The subsequent distillation and purification must be conducted as previously described.

By far the best as well as the safest plan for preparing hydrobromic acid is to distil a mixture of bromide of potassium and phosphoric acid. A retort should be fitted with a cork at its extremity, and a tube sloping upward (as also should the retort itself), and so bent that the gaseous acid which is evolved may pass through a bottle of distilled water. In the retort are placed some dry powdered crystals of pure bromide of potassium, and over this is to be poured a concentrated solution of phosphoric acid. Heat is now applied when the gaseous hydrobromic acid comes over in great abundance, and is rapidly condensed in the water through which it passes. The resulting solution forms a colourless, strongly acid, fuming liquid of considerable density. In its most concentrated form it has a specific gravity of 1·29. A very strong acid, when boiled becomes weaker, whilst a weak acid becomes stronger on boiling; the ultimate produce of boiling hydrobromic acid of any strength being the same. An acid of this strength has a specific gravity of 1·486, and contains about 47 per cent. of the anhydrous acid, being represented symbolically by the formula HBr, 10HO. It boils at 259 F., and may, of course, be distilled unchanged.

The impurities likely to be present in commercial hydrobromic acid, are phosphorous, hydrochloric acid, sulphur compounds, free bromine, and organic compounds. The *phosphorous* may arise from insufficient purification. It is best detected by adding an equal volume of nitric acid to the suspected acid, and, after boiling together for a few minutes, to evaporate to dryness at a gentle heat. If phosphuretted compounds had been present, the nitric acid would have oxidised them into phosphoric acid, which would be left behind as a colourless syrupy mass on evaporation. This residue when dissolved in water should be tested for acidity by means of blue litmus paper. If it be acid, ammonia in excess should be added to it, then a drop of sulphate of magnesia solution, when a white crystalline precipitate shows the presence of phosphoric acid. *Hydrochloric acid.*—This impurity may be present owing to the bromine not having been properly purified from the chlorine used in its separation. It can only be detected by a difficult and rather complicated chemical process quite beyond the powers of any one but an experienced chemist to perform. This part of our subject would not, however, be complete were the process to be omitted, and we therefore give it for the benefit of our chemical readers. The acid is to be first neutralized with carbonate of soda and then evaporated to dryness. The dry white residue is then to be mixed with an equal bulk of bichromate of potassa, and well powdered together. The mixture must now be placed in a perfectly dry test tube to which is fitted a cork and bent glass tube, which leads to another perfectly dry tube surrounded with cold water. Oil of vitriol is then to be added to the mixture in the first test tube and heat applied by means of a spirit lamp. Dark red vapours will be evolved which will pass through the bent glass tube, and condense in the dry test tube in the form of a dark red liquid. This liquid consists of bromine, and (if hydrochloric acid has been also present) of chloro-chromic acid. Water is now to be added to the liquid and then excess of ammonia. The bromine will be dissolved in the alkali with formation of a colourless liquid, but chlorochromic acid will be decomposed and dissolved forming a *yellow* solution. If therefore the liquid after addition of ammonia be of a yellow colour, it is proof that chlorine is present. The *sulphur compounds* may be present if the hydrobromic acid has been prepared by a method which is sometimes adopted, namely by passing hydrosulphuric acid through a mixture of bromine and water. This is a bad method and should never be used, as, however, it is attended with no great difficulty, it is sometimes employed, and consequently commercial acid should always be tested for this injurious body, sulphur, unless the respectability of the maker of the acid is sufficient guarantee that proper means of preparation have been adopted. Add nitric acid to the suspected acid, and boil for some time, as in the case of the phosphoric acid, then add a drop or two of chloride of barium and dilute the liquid with three times its volume of distilled water. If there is a permanent white precipitate, it will be sulphate of baryta and will show that sulphur has been present in the hydrobromic acid. *Free bromine* has already been alluded to as likely to be present from the volatilisation of the bromine used in the preparation of the acid. It may readily be removed by shaking with metallic mercury, or by adding a slight trace of soda or potash and redistilling. Its presence may also be at once seen by the orange red colour which it communicates to the acid. If the presence of the bromine were only caused by the volatilisation of this element in the process making, it would not be an impurity of much consequence; but pure hydrobromic acid itself gradually absorbs oxygen from the atmosphere, and liberates bromine, and this being constantly removed by mercury or alkali gradually weakens the acid until scarcely anything is left but pure water. *Organic compounds* may also be present in commercial hydrobromic acid if it is prepared, as is sometimes the case, by the action of bromine on alcohol. These have a peculiar, and, in some cases, a very powerful smell. In the ordinary state they would not, however, be detected by this test, as their odour would be marked by that of the acid. The latter must, therefore, be neutralised by the cautious addition of caustic potassa, care being taken to avoid a great excess, when the peculiar odour of the organic products will be at once apparent.

COLLODION MUST BE ACID AND CONTAIN FREE IODINE.

It is assumed by most photographers that collodion to act quickly must be, as much as possible, exempt from acid and free iodine; nevertheless, all collodions which act well are both acid and coloured by free iodine.

Acid in excess in the nitrate of silver bath, in the collodion, and in the developing agent, is the cause of the pictures being formed very slowly, and for this reason also the total absence of a picture sometimes occurs; in this case the collodion is intact, and retains its beautiful opaline colour. Excess of acid is, therefore, injurious; but to insure success, and also to obtain the maximum rapidity, a certain amount of acid must be present in the silver bath, in the collodion, and in the reducing agent, besides free iodine in the collodion.

I have recently had occasion to prove the necessity for this. Having undertaken a research upon sulphate of iron-developing agents. I passed a whole day without being able to obtain the slightest trace of an image, as the picture became suddenly fogged, and, after washing with hyposulphite, presented a bright metallic appearance. I really did not know what to do. I even looked through my lens into the camera, to see if the light found admission anywhere. As my silver bath was the same as I had employed the day before, and with the same collodion, had given good pictures with any kind of preparation of sulphate of iron for developer, I was induced to believe that the evil arise from the new preparations of sulphate of iron, which I had varied in every possible manner. I had them red, yellow, green, and brown, which I acidulated more and more. At last, I recollected that I had added some fresh normal collodion to that which I had used the previous day, with the view of rendering it thicker. I was very far from supposing that this had anything to do with my failures; but in making use of some collodion to which no addition of normal collodion had been made, all my sulphates gave good pictures, and the rebellious collodion, after being mixed with a *red* collodion, very slow of itself, gave good proofs with the same sulphates.

Thus, there is sometimes formed in normal collodion, a reducing compound, such as aldehyde, formic acid, &c., which must be neutralized by the addition of an *acid*, or of *iodine in excess*. The addition of an acid does not always turn the collodion red; crystallizable acetic acid for example does not redden collodion even after several days, and added in very small quantities, one or two drops to the ounce of collodion, is an excellent means of preventing fogged pictures.

The addition of iodine produces the same effect, but the dose must be a minimum one. Generally, good collodion has a lemon colour when in small bottles, but which becomes orange when in large bottles; and if we drop a little collodion that works well upon a piece of test paper, it will always be found to show an acid reaction.

The nitrate of silver bath must also be acid, especially when employing iron developers. It has been almost impossible to obtain anything passable with a silver solution neutral to test paper; but upon adding one or two drops of nitric acid, sufficient to redden the test-paper, all went well, and better still when the collodion contained acetic acid.

Therefore, reducing agents must be banished from collodion as well as from the nitrate bath. This fact naturally brings me to M. Ferrier's case, in which he announced to the Paris Photographic Society, that he obtained his instantaneous views through the addition of formic acid to the nitrate of silver-bath. After satisfying myself by numerous experiments that the addition of formic acid to the nitrate bath is always followed by a general fogging of the plate, and the complete absence of a picture, and being persuaded that M. Ferrier knew that fact as well as I did myself, I oudly protested against his statement. If the formic acid be added to the reducing agent, and not to the nitrate bath, the condition of things is entirely changed.* M. Ferrier says that the error of statement was a misprint; if it were so, he ought immediately to have announced it through the journals, and not led a host of experimental photographers into a course of profitless trials. As for myself, I was greatly irritated at having been led through his error or mis-statement, into spoiling my baths, and expressed my feelings rather strongly. It is more than probable that M. Ferrier never put formic acid into his silver solution.—*La Lumière.*

GLYCERINE IN COLLODION.

BY M. A. GAUDIN.

Photography, so long as it is confined to obtaining very pure negatives upon wet collodion, if we disregard sensibility, presents no difficulty; but from the moment we wish to obtain the greatest sensibility, the task becomes difficult. For a good, rapidly-obtained negative to become suddenly *fogged*, is no unfrequent occurrence, without our being able to trace the cause of it. This kind of failure is not peculiar to photography. All the perfected arts require similar delicate precautions, that is to say, an operation of great complexity, the knowledge of which has been obtained by multiplied researches. A simple touch of the painter's pencil on a picture, although appearing the simplest thing in the world, is really a very complex operation. It requires that the painter first prepares the proper hue of colour, to which end he must select the proper pigments, and mix them, not by weight, but by the eye, according to his judgment. For the application of the touch, the difficulty is as great; it must occupy a precise spot, which cannot be measured by the compass, but rather by the artistic feeling of the painter, who takes into consideration the effect of the slightest touch upon the general effect of the pictures. So, also, in photography; all the agents employed are allied and dependent upon each other; it is necessary that the same harmony exists between them as between the touches in a painting; and often, a single drop of a substance suffices to destroy the equilibrium when we are on the eve of perfection, as in the picture of a master, the least discordant touch becomes a spot.

By analogy also, there exists an infinity of possible combinations between the chemical agents of photography, as between the colours used by the painter, consequently, this subject will never become exhausted.

For example, after having employed glycerine in the the silver bath with some success, I was naturally prompted to try its effects when added to collodion and to the reducing agent. In adding it to the collodion, I had in view the increasing the porosity of the latter, but I hesitated to employ it, supposing that it would act like *water*, by destroying the cohesion of the collodion. Experience has furnished a decidedly opposite result, for I have been able easily to transfer to paper an ordinary collodion to which glycerine has been added. Glycerine may be added to collodion in the proportion of five per cent., without impairing its qualities, while it singularly facilitates its filtration through paper. This collodion, recently mixed with glycerine, yields pictures of unexceptional purity, without any apparent diminution of sensibility, *on the same day* they are mixed, but I strongly suspect that the collodion becomes very slow on the morrow, for, upon two trials, I have been so satisfied with the addition of glycerine that I mixed it with all my collodions; but next day, I remarked that they acted much slower, which could proceed from no other cause. I propose to clear the question by dividing a bottle of collodion into two equal portions, and adding 5 per cent. of glycerine to one, and operating with both, side by side, on the same plate, on the same day, and on the morrow.—*La Lumière.*

* Our readers, on looking back, will find that the announcement in our pages stated that the formic acid should be added to the developer.—Ed.

Photographic Tourist.

MY FIRST PHOTOGRAPHIC TOUR.

If, under the head of "Photographic Tourist," the following brief narrative of my first experiment in that direction may legitimately claim space, you are heartily welcome to these pages. They go a little out of the usual track, but they may not be altogether uninteresting to your readers, who perhaps may even appreciate their novelty.

I may as well begin by confessing how in the year —48 I emerged from a state of apprenticeship and began to "look around and choose my ground," in order to start in life and win bread as one of the smaller fry of street-exhibiting miniature painters. How I took apartments in a leading London thoroughfare,—hung out at the street door a small mahogany case containing a few elaborately stippled water-colour sketches and ivory miniatures—and how, I being a poor, *lonely*, friendless fellow of nineteen, my next *prudent* step was to *get married!*

Well, every miniature painter can tell you how that must have ended. Our brother painter, Daguerre, had doomed us to destruction. Bill and Tom, and Bob and Jack, came from bench, and shop, and desk, leagued photographically for our extermination. Charming little homes, on first and second floors, where the refining and beauty-creating power of soul-bewitching art brought humble means but pleasant cheerfulness to its lowliest votaries, were broken up, or became miserable dungeons, in which shabbiness of garments locked-up poor wretches, trembling at the steps of cash-demanding landlords and merciless duns; in which poor wives bravely restrained their own bitter tears the better to wipe away those from the eyes of their (at least at such times commonly) weaker, if not "worser," halves; and in which poor little children grew accustomed to going supperless to bed. Ours was not, perhaps, the worst of such cases—for we had no children—but, egad, I thought it bad enough: and many a time did I and my poor little dearie—a mere boy and girl—look tearfully along our future path into that narrow black tunnel as it went tapering away into the far distance to a spark of light which, indicating the way out, we fondly called "*some* hope;" without which—Ah, well! that's all over now, and has no right to be here recalled.

There was only one way out of the mess we, poor young loving fools, were in. We took it—that is to say, we did sell everything we had of any value, and we did'nt pay the rent of three quarters of a year, for which, by the by, I had already been summoned—and by so doing we were enabled, that is to say I, as representing both, to visit a certain photographer, receive lessons in photography, and get him to procure us the necessary apparatus.

This photographer was not exactly a first-class one, but such as he was his charges were more within the scope of our paltry means. (I afterwards understood that, previous to the introduction of the daguerreotype, he flourished cross-legged on a tailor's shop-board). He was a small, thin-faced man, with a large moustache and a rough head of long, straight hair. There was an air of no small consequence about him, when I called upon him, and, though he appeared in a scarlet smoking cap, and an elaborately-braided velvet morning coat, his speech at once betrayed that his education had *not* been conducted at either of our Universities. In his way of doing business there was, I found, much of the Jew salesman blended with an exaggerated, ludicrous, and caricatured imitation of the artists' pride, and such a strong dash of the loftily wonderful, mysterious, and magical, as an alchymist who had discovered the philosopher's stone, and was not going to part with it for any trifling considerations, might have displayed.

When I first saw him develop the image over the mercury I was curious to understand the theory of this process.

"Blest if I know," said this great Israelitish-wizard-artist being. "All that I knows about it is, that when I put this 'ere plate in that there place, somehows or another it brings out the pictur'."

Such a very lucid explanation wasn't *quite* satisfactory; but, perhaps, it would not be so very difficult, even now, to point out not a few photographers whose ideas—despite the efforts of journals and societies—are in a similar indefinite condition as to the rationale of their art.

So I received my lessons, mastered the laborious mysteries of rouge and tripoli in cleaning and polishing, or buffing the plates; learnt how the same were to be iodized and bromined; how they were to be exposed, and how, by the aid of a spirit-lamp and the mercury-box, I could "bring out the pictur'," which knowledge cost me, I think, £20.

When all these tremendous secrets, so guardedly and jealously shielded from less-privileged beings, were in my possession, I got my worthy instructor to procure me the cheapest possible set of useful apparatus, a wish of mine which he most religiously observed, for I doubt if a cheaper (or more worthless) set could have been found in the shop of any dealer in such goods. Although the spirit of my wish was certainly somewhat lost sight of in his charging me for this same apparatus, just as much as would have purchased a first-rate set of a first-class dealer. I, however, paid my money cheerfully, and readily enough (although it was just a little less than all I had), for did not my talented instructor ostentatiously parade the generous nobility of his artist-like nature, by repeatedly calling my attention to the dealer's receipt, for the cash paid, as a proof of the absurd trifle he got, by way of per centage, in purchasing and making choice of the same, at the expense of so very much of his most precious time, and such very great trouble.

Not long ago I was talking over this affair with this very identical dealer.

"Oh, the cunning rogue," said he, "I thought that was why he used to induce me to give receipts for more money than he paid for articles, ha! ha! ha! ha!"

As he spoke thus, and laughed aloud, I thought gravely of my poor wife, and of our hard, hard struggles in consequence of the above robbery, and was sorely tempted to give this dealer, as some folk say, "a bit of my mind," but I did not, although I have never since visited his shop.

And thus, then, did I prepare to start upon my first photographic tour. I must confess that I did not take kindly to the new art-science, for all my more ardent aspirations pointed the artist painter's way, and it cost me no small effort to resign the earliest love of my heart and lay down the palette, pencil, and brush, for metal plates and chemicals.

I had worked hard and perseveringly, and in the face of more obstacles than I can here describe, to acquire the profession, which thus failed me in my sorest need. I used to go to my master's studio at 8 in the morning, and leave at the same hour in the evening, to hurry to my not particularly elegant or stylish home (one room in the back of a narrow back street's house), and get to my pencils and desk. Copying from prints or paintings, or from the round; and, when I could afford a model, from the nude. I went in ambitiously for all branches of artistic study, including anatomy—that is to say, so far as I could from the few books, &c.* I contrived to borrow, and I used to sit up night after night until the eager and absorbing interest of my work gave way to the sensation of fatigue, and I could jump into my bed and a sound dreamless slumber at one and the same time. So you must confess I had some excuse for the sad feelings I experienced in deserting the darling profession I had so earnestly and lovingly prepared myself for, and turning all my energies and efforts into a fresh and uncongenial channel.

To return. We made up our minds to start on our tour through the eastern counties, as "photographic artists," and we had circulars duly prepared, stating that Mr. and Mrs. S— from ——, London, informed "the nobility, gentry, and inhabitants of Chelmsford," &c., &c., with a few poetical lines about securing "the shadow ere the substance fade," &c., quoted, doubtless, from some eminent poetic authority, together with a list of prices, and having completed the packing of our boxes one eventful night, we sat up, talking cheerfully and hopefully of the future until morning broke, lest we should be too late for the earliest train. We chose Chelmsford for our first starting point, for this very sufficient reason, it was not far, and we could land there with at least one bright-eyed sovereign in our possession, upon which we knew a longer journey would have made very serious inroads.

R. A. S.

SUN-PAINTING AND SUN-SCULPTURE.

BY OLIVER WENDELL HOLMES.

There is one old fable which Lord Bacon, in his "Wisdom of the Ancients," has not interpreted. This is the flaying of Marsyas by Apollo. Everybody remembers the accepted version of it, namely,—that the young shepherd found Minerva's flute, and was rash enough to enter into a musical contest with the God of Music. He was vanquished, of course, and the story is, that the victor fastened him to a tree and flayed him alive.

But the God of Song was also the God of Light, and a moment's reflection reveals the true significance of this seemingly barbarous story. Apollo was pleased with his young rival, fixed him in position against an iron rest (the *tree* of the fable), and took a *photograph*, a sun-picture of him. This thin film or *skin* of light and shade was absurdly interpreted as being the *cutus*, or untanned leather integument of the young shepherd. The human discovery of the art of photography enables us to rectify the error and restore that important article of clothing to the youth, as well as to vindicate the character of Apollo. There is one spot less upon the sun since the theft from heaven of Prometheus Daguerre and his fellow-adventurers has enabled us to understand the ancient legend.

We are now flaying our friends and submitting to be flayed ourselves every few years, or months, or days, by the aid of the trenchant sunbeam which performed the process for Marsyas. All the world has to submit to it—kings and queens with the rest. The monuments of Art and the face of Nature herself are treated in the same way. We lift an impalpable scale from the surface of the Pyramids. We slip off from the dome of St. Peter's that other imponderable dome which fitted it so closely that it betrays every

* South Kensington Museum was then, alas! not in existence.

scratch on the original. We skim off a thin, dry cuticle from the rapids of Niagara, and lay it on our unmoistened paper without breaking a bubble or losing a speck of foam. We steal a landscape from its lawful owners, and defy the charge of dishonesty. We skin the flints by the wayside, and nobody accuses us of meanness.

These miracles are being worked all around us so easily and so cheaply that most people have ceased to think of them as marvels. There is a photographer established in every considerable village,—nay, one may not unfrequently see a photographic *ambulance* standing at the wayside upon some vacant lot where it can squat unchallenged in the midst of burdock and plantain and apple-Peru, or making a long halt in the middle of a common by special permission of the "Selectmen."

We must not forget the inestimable preciousness of the new Promethean gifts because they have become familiar. Think first of the previlege we now have of preserving the lineaments and looks of those dear to us.

"Blest be the Art which can immortalize,"

said Cowper. But remember how few painted portraits really give their subjects. Recollect those wandering Thug of Art whose murderous doings with the brush used frequently to involve whole families; who passed from one country tavern to another eating and painting their way—feeding a week upon the landlord, another week upon the landlady, and two or three days apiece upon the children; as the walls of those hospitable edifices too frequently testify even to the present day. Then see what faithful memorials of those whom we love and would remember are put into our hands by the new art, with the most trifling expenditure of time and money.

This new art is old enough already to have given us the portraits of infants who are now growing into adolescence. By-and-by it will show every aspect of life in the same individual, from the earliest week to the last year of senility. We are beginning to see what it will reveal. Children grow into beauty and out of it. The first line in the forehead, the first streak in the hair are chronicled without malice, but without extenuation. The footprints of thought, of passion, of purpose, are treasured in these fossillized shadows. Family traits show themselves in early infancy, die out, and reappear. Flitting moods, which have escaped one pencil of sunbeams, are caught by another. Each new picture gives us a new aspect of our friend; we find he had not one face, but many.

It is hardly too much to say, that those whom we love no longer, leave us in dying, as they did of old. They remain with us just as they appeared in life; they look down upon us from our walls; they lay upon our tables; they rest upon our bosoms; nay, if we will, we may wear their portraits, like signet-rings, upon our fingers. Our own eyes lose the images pictured on them. Parents sometimes forget the image of their own children in a separation of a year or two. But the unfading artificial retina, which has looked upon them, retains their impress, and a fresh sunbeam lays this on the living nerve as if it were radiated from the breathing shape. How these shadows last, and how their originals fade away!

What is true of the faces of our friends is still more true of the places we have seen and loved. No picture produces an impression on the imagination to compare with a photographic transcript of the home of our childhood, or any scene with which we have been long familiar. The very point which the artist omits, in his effort to produce general effect, may be exactly the one that individualizes the place most strongly to our memory. There, for instance, is a photographic view of our own birthplace, and with it a part of our good old neighbour's dwelling. An artist would hardly have noticed a slender, dry, leafless stalk which traces a faint line, as you may see, along the front of our neighbour's house next the corner. That would be nothing to him, but to us it marks the stem of the *honeysuckle-vine*, which we remember, with its pink and white heavy-scented blossoms, as long as we remember the stars in heaven.

To this charm of fidelity in the minutest details the stereoscope adds its astonishing illusion of solidity, and thus completes the effect which so entrances the imagination. Perhaps there is also some half-magnetic effect in the fixing of the eyes on the twin pictures,—something like Mr. Braid's *hypnotism*, of which many of readers have doubtless heard. At least the shutting out of surrounding objects, and the concentration of the whole attention, which is a consequence of this, produce a dream-like exaltation of the faculties, a kind of clairvoyance, in which we seem to leave the body behind us and sail away into one strange scene after another, like disembodied spirits.

"Ah, yes," some unimaginative reader may say; "but "but there is no colour and no motion in these pictures you think so life-like; and at best they are but petty miniatures of the objects we see in Nature."

But colour is, after all, a very secondary quality as compared with form. We like a good crayon portrait better for the most part in black and white than in tints of pink and blue and brown. Mr. Gibson has never succeeded in making the world like his flesh-coloured statues. The colour of a landscape varies perpetually with the season, with the hour of the day, with the weather, and as seen by sunlight or moonlight; yet our home stirs us with its old associations, seen in any and every light.

As to motion, though, of course, it is not present in stereoscopic pictures, except in those toy-contrivances which have been lately introduced, yet it is wonderful to see how nearly the effect of motion is produced by the slight difference of light on the water, or on the leaves of trees as seen by the two eyes in the double picture.

And lastly, with respect to size, the illusion is on the part of those who suppose that the eye, unaided ever sees anything but miniatures of objects. Here is a new experiment to convince those who have not reflected on the subject that the stereoscope shows us objects of their natural size.

We had a stereoscopic view taken by Mr. Soule, out of our parlour window, overlooking the town of Cambridge, with the river and the bridge in the foreground. Now, placing this view in the stereoscope, and looking with the left eye at the right stereographic picture, while the right eye looked at the natural landscape, through the window where the view was taken, it was not difficult so to adjust the photographic and real views that one overlapped the other, and then it was shown that the two almost exactly coincided in all their dimensions.

Another point in which the stereograph differs from every other delineation is in the character of its evidence.

A simple photographic picture may be tampered with. A lady's portrait has been known to come out of the finishing artist's room ten years younger than when it left the camera. But try to mend a stereograph, and you will soon find the difference. Your marks and patches float above the picture and never identify themselves with it. We had occasion to put a little cross on the pavement of a double photograph of Canterbury Cathedral, copying another stereoscopic picture where it was thus marked. By careful management the two crosses were made perfectly to coincide in the field of vision, but the image seemed suspended above the pavement, and did not absolutely designate any one stone, as it would have done if it had been a part of the original picture. The impossibility of the stereograph's perjuring itself is a curious illustration of the law of evidence. "At the mouth of *two witnesses*, or of three, shall he that is worthy of death be put to death; but at the mouth of one he shall not be put to death." No woman may be declared youthful on the strength of a single photograph; but if the stereoscopic twins say she is young, let her be so acknowledged in the high court of chancery of the God of Love.—*Atlantic Monthly.*

GUN-COTTON FOR COLLODION.

BY COLEMAN SELLERS.*

That wonderful property possessed by cotton, in common with other vegetable fibres, of being converted by acids into a substance soluble in ether and alcohol, makes it invaluable to the photographer; but, to judge by the amount of writing on the subject from the pens of so many able chemists, there must be great uncertainty in its preparation to make it fit for our use. Few authors venture to give a fixed formula for its manufacture, and few amateurs, reading of the many difficulties and dangers, venture on experiments. For my own part, after a few trials, I was well content to purchase what I should need from reliable chemists, and have generally been well satisfied with its working. There has always, however, been a desire on my part to try it again, on certain conditions, and the principal one was, that I should have the cotton thoroughly bleached. Here was the great trouble, and my want of knowledge in the bleaching line prevented my attempting this part of the experiment. I had seen cotton boiled in alkalies, and then well washed and dried; but still it did not become the pure article I wanted as the ground-work.

Chance, however, brought me in contact with one who could supply this want. Mr. J. Hunter, whose extensive bleaching works near Philadelphia, evince his thorough knowledge of the art—becoming interested and rapidly proficient in photography, entered at once into the spirit of my experiments, and volunteered to furnish the cotton, which he treated thus:—Having selected the best article of cotton he could find, he took it as it came from the cards, as clean as machinery could make it. He then quilted it in between two muslin cloths about one yard square. These quilts were then put into the bleacher's hands, and were nearly a week undergoing the various processes. When they reached me, nothing could be whiter or purer than the cotton seemed to be, its characteristic peculiarity being a wonderful capacity for absorbing moisture. If a bunch of it was held so as to touch the surface of water, the fluid would at once rise into the mass by capillary attraction, in great contrast to the action of raw cotton under similar circumstances, which will repel water like a duck's back.† It was so hard and crisp that it would not have been possible to re-card it. Hence it had a more matted look than raw cotton usually has, but was easily picked apart with the fingers.

Allow me here to remark, that it at once occured to me that there were many uses to which this cotton could be put to besides making gun-cotton, as, for instance, to dentists it would be invaluable for drying cavities of teeth previous to the insertion of the plug, and some were placed in the hands of a good dentist, who pronounced it excellent. I am yet in hopes that he, or some other dentist, who has tried it, will bring it to the notice of the dental college, so that there may be a demand for the article, and it can be prepared in large quantities, both for their use and that of photographers.

To return to the subject. It was with intense satisfaction I found that, when immersed in the mixed acids, there was no coaxing required to make the acids penetrate, but it would sink to the bottom of the vessel immediately. The next step was to devise a convenient form of vessel to mix the acids in, and to keep them up to their proper temperature. This was soon done by selecting, from the culinary department at home, two yellow glazed pudding bowls—one larger than the other—the smallest one holding about two quarts. The larger one being partially filled with boiling water, the smaller one was placed in it; into this was poured ten ounces of commercial sulphuric acid; stirring it with the thermometer, the temperature of the acid soon rose to 100°. I then added ten ounces of fuming nitric acid; the temperature at once arose to 165°; allowing it to subside to 150° the cotton was immersed enough to be well covered by the acid; pushing it well below the surface with glass rods, and, having covered the bowl with a dinner plate, let it stand for ten minutes, at the end of which time, the temperature was still 150°. Next, by the aid of a plate of glass three inches wide and twelve long, and a three-eighth inch glass rod, bent to a hook at one end, the cotton was lifted in a mass from the acids, and held to drain for a few moments, then plunged into a bucket of water, placed conveniently near, stirred about quickly, removed from this water into another bucket-ful near by, and then washed for a few minutes in the hands under the hydrant; next, renewing the boiling water in the outside bowl and adding two ounces more of sulphuric acid to the bath, I fed in a new lot of cotton, putting it through the same process as the first.

These cottons were then placed in a large glass funnel under the tap, well protected on the top by white flannel which served as a filter, and in this manner washed by a constant stream of water sinking through the mass for twelve hours, then dried in the artificial heat of a warm room. So far for the way to make the gun-cotton.

This cotton, in the hands of several good operators, was pronounced excellent, and its good qualities may be attributed to chance; but with the same lot of bleached cotton the same process was repeated at different times, but in exactly the same manner, always, however, using samples of acids from different manufactories. This was done to see if a slight difference in the acids would affect the result; but it did not.

The manner of heating the acids in a hot-water bath is, I have no doubt, practised by others, and is much better than using a spirit lamp, the large amount of hot water surrounding the dish being slow to cool. All the samples of cotton were sensitized in the same manner, and as the mode of sensitizing was rather peculiar, I will venture to give it.

The result of all my experience has been to confirm me in the use of the iodide and bromide of ammonium exclusively, and in no case do I ever, for any kind of work, use the salts of other metals. The quantity of collodion prepared at one time, is always one pint, never more or less. Bromide of ammonium is not soluble in absolute alcohol; but it is essential in making good collodion to have the alcohol as nearly absolute as possible. Hence I have adopted the following formula:—Into a clean graduate measure pour seven ounces of absolute alcohol; into this put sixteen grains of bromide of ammonium; stir with a glass rod, and endeavour to make it all dissolve; this cannot be done if the spirit is pure. Add a few drops of water and stir again, thus adding water, drop by drop, until it has taken up all the salt; next make up the bulk to eight ounces with alcohol; this ensures the alcohol having just enough water and no more. Into this stir eighty grains of iodide of ammonium, which will dissolve freely. Put into a clean bottle sixty-two grains of dry gun-cotton, and pour over it the sensitized alcohol; shake very well, and add eight ounces of concentrated sulphuric ether. The cotton will rapidly dissolve, and the collodion can be set aside in a cool dark cellar to settle, and will be ready for use in about three days.

In conclusion, let me call the readers attention to a fact in relation to collodion, first brought to my attention by Dr. C. M. Crenou, of Philadelphia, and to whom I am sure is due the discovery. If collodion, when freshly sensitized, be put aside to settle, and not disturbed in the least for several days, and then, when pure, if the first inch in depth in a pint bottle be drawn off carefully with a syphon into a clean bottle, it will be found to be very much more sensitive than the remainder.* The separation of this extra-fine collodion from the bulk does not seem to injure the balance. Hence it is an excellent plan to draw off this portion and set it by labelled for instantaneous photography.

* Condensed from *Humphrey's Journal.*

† One of the early difficulties encountered by Mr. Hardwich in his experiments, was the presence of a resinous coating on the fibre of the raw cotton, which he got rid of by boiling with caustic potash. Some experimentalists have conceived, however, that this resin acted on by the acids, communicated valuable properties to the resulting pyroxyline, and have, therefore, for other reasons than the extra trouble, declined to purify the cotton before submitting it to the acids.—Ed. Photographic News.

* This is a circumstance we have known to be verified in the experience of more than one intelligent photographer.—Ed. Photographic News.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 31st July, 1861.

Since we are never sure what construction may be put on our actions, it behoves us, especially while acting in a public capacity, to proceed with the utmost prudence and caution, so that no possibility may arise of our motives being impugned.

The secretary of your parent photographic society recently addressed a letter to the secretary of the Paris Photography, in which—taking into view the programme as originally issued by the Royal Commission of the forthcoming Great Exhibition—he urged that the proper course for (French) photographers to pursue would be *not to send any works to the Exhibition at all!* it being assumed by the London secretary that photographs were to be hopelessly consigned to the limbo of "machines, utensils, and scientific apparatus." It, however, unfortunately happened that Dr. Lyon Playfair's letter was brought before the society also at the same time as the London secretary's. As is well known, assurance is given in Dr. Playfair's letter that photography will doubtless occupy that place in the Exhibition to which it is unquestionably entitled among the fine arts. The astonishment of our society at the strange discrepancy between the two letters may be more easily imagined than described, and the natural conclusion is that the disingenuous letter of the London secretary is only a *ruse* to keep French photographers from sending their pictures to the Exhibition, and the natural inference is that British photographers are fearful of the consequences of the rivalry, which I, for one, am not at all disposed to admit. It is impossible to avoid the conclusion that the London secretary wrote with a sinister motive, but what that motive may have been is the secretary's secret, and the one assigned seems to be the only one that can harmonize with his extraordinary statement and recommendation.

M. Aimè Girard remarked that he could not help expressing his astonishment upon comparing the singular proposal of the London Photographic Society with the explicit language of Dr. Lyon Playfair, who, he was sure, must be regarded as the most competent person to judge in all matters relating to the classification of the Exhibition, and he thought there would be great danger to the interests of French photography in adopting Dr. Diamond's suggestion.

M. Laulerie, our secretary, said that under any circumstances, the worst kind of protest they could make against the classification of photographs in the Exhibition would be that of abstaining from sending any pictures to it; the very best protest, as it appeared to him, would be to send to London such a collection of brilliant photographs as would effectually convince the Royal Commission of its error.

The president of our society (M. Regnault) fully coincided with the opinions expressed by M. M. Girard and Laulerie. The high position of Dr. Playfair, his part in the organization of the Exhibition, gave the highest value to his letter, and rendered it more than probable that the demand made by the London Photographic Society would be successful. He added, in support of an opinion emitted by M. Robert of Sèvres, that as the French Photographic Society was not in communication with the Royal Commission for the Exhibition, it could only act through the Imperial Commission charged with organizing the French Section of the Exhibition, and therefore he proposed :—

1st. To address the secretary of the London Photographic Society, a letter embodying the views of the meeting.

2nd. To confer on the committee of administration full powers to act in this affair according as circumstances may require.

These propositions on being put to the vote, were unanimously adopted.

Mr. Cordier has communicated the following in the preparation of positive paper :—

To avoid the use of a bath of silver of 20 per cent. and at the same time to retain all the brilliancy of the albumenized proofs, and secure their preservation either before or after sensitizing, in Marion's boxes; he first coagulates the albumen by immersing the paper in the strongest and purest alcohol possible. Coagulation by dilute nitric acid, or by a heat of 212° alone, is useless; the proof, when the paper is afterwards placed in water, loses all its albumen, and consequently becomes dull and flat; with alcohol it is just the reverse. We sensitize the paper subsequently in a bath of crystallised nitrate of 5 per cent., which, not dissolving the albumen, keeps in good condition. If the experiments of other photographers confirm those of M. Cordier, it will be easy to avoid even the simple manipulation suggested, by requiring dealers to furnish the photographer with albumen paper, *coagulated by alcohol*. The cost is very trifling.

Count Schouwaloff has communicated to our Photographic Society the following method of obtaining positives by carbon printing.

He takes the usual gelatine solution, but doubles the quantity of carbon (lamp black) usually added to it, and diminishes the quantity of water. This solution is applied with a soft brush to a sheet of paper, and quickly dried by the application of a gentle heat.

The paper thus prepared is put into the printing-frame, the white side of the paper in contact with the negative. After exposure to the light, the proof is placed in a dish, gelatine side downwards, and hot water poured upon it. At first the black and opaque coating does not appear to be attacked; but, in a few minutes, upon being gently rubbed under water with a soft brush, the proof is brought out in a moment, and only requires rinsing in clean water.

This method, besides being simpler in manipulation than any other proposed for photographic printing, is also quite permanent; but it has the twofold disadvantage of reversing the image, and of being produced through the substance of the paper, thereby losing in sharpness.

I do not think the latter of these objections to be a very serious one, except in such cases as when an extraordinary degree of sharpness is required. With regard to rectifying the position of the image, this defect may be overcome by exposing the printing frame, not to ordinary light, but to the solar light, emanating from a Woodward's apparatus.

The shadows of the proof now obtained are so sharp, that it appears to me the image would traverse the double thickness of the glass and the paper without deterioration.

We can, therefore, in order to rectify the image, reverse the negative in the printing-frame.

The committee appointed to examine M. Anthoni's portable laboratory, for obtaining wet collodion pictures in the open air, report favourably. They think the apparatus is very ingenious, and calculated to be very serviceable, especially in taking instantaneous pictures; it is quite light and of portable dimensions.

A Photographic Exhibition will open at Marseilles on the 1st of September next, and the 15th of August is the last day upon which articles intended for exhibition can be received. No universal photographic exhibition has hitherto taken place in the South of France. The geographical position of Marseilles, together with its commercial relations, render it an important centre for communications with all nations; and the forthcoming exhibition cannot fail to extend the boundaries of photography. All professional and amateur photographers are invited to send pictures and apparatus to the care of the Secretary of the Photographic Society of Marseilles, previous to the date abovementioned.

M. de Luca obtains oxygen gas economically by passing the vapour of sulphuric acid through a porcelain tube heated to redness. The acid is put into a tubulated retort three-fourths filled with pumice stone, the stopper and joints are secured with asbestos and clay.

THE MEASLES IN ALBUMENISED PAPER.

Dear Sir,—Having heard from several of my friends that I have fallen into a great error as to the name I employed to designate the appearance in albumenised paper whilst toning, described in a former article, that the effect is usually called by the name of Mealyness, and that the measles is applied to a print improperly fixed, through being left too short a time or in too weak a solution of hypo, being dark spots seen upon looking through the paper. I beg to reply, that an immortal bard has said, "A rose by any other name would smell as sweet," therefore I suppose a photographer may justly exclaim, "A fault by any other name would be as bad." However, it is just as well that all should be agreed as to a name for a certain thing, that all may recognise it when they see it. To proceed, however, to practical remarks, I am happy to hear that numerous persons are getting over their troubles by the employment of the acetate of soda with the chloride of gold, as I cannot help thinking that by its employment or the citrate of soda, a great step in advance in lessening our difficulties is in progress; and if we are a little particular in choosing a paper with a fine texture, we shall hardly ever have to complain of want of success. The other effect, although one I did not think of mentioning, as all must know how to remedy it, leads to a no less important discussion; the question being how much hypo is really sufficient to fix a given quantity, say every whole sheet of paper. This has been satisfactorily answered by Mr. Dawson at the North London Society's meetings. That gentleman found that one part of chloride of silver was fairly and fully dissolved in three parts of hypo; now the amount of chloride of silver will slightly vary in different sheets of paper according to the absorbing nature and the thickness of the albumen employed, but I think its maximum may be taken at 30 grains or ½ a drachm, so that it will take 1½ drachms, or say ¼ ounce of hypo to fix each whole sheet of paper. Now comes the difficulty; how much water are we to employ? It is certainly not safe to use weaker than 10 per cent. of hypo; thus supposing we take 40 ounces of water, that will require 4 ounces of hypo, which, according to our calculation, will fix 16 sheets of paper. Now we cannot put more than two sheets cut up at a time, into this amount of liquid, and it will be therefore very slow work fixing, or we must employ a larger amount of solution. Hypo is now certainly very cheap, and there is not much loss in value in throwing it away; but there is another loss of far greater importance. All who have toned on a large scale, must have observed, that fresh hypo dissolves out a good quantity of the gold toning, until it becomes saturated with it. Thus, in the above quart of solution, the first two sheets would be, when fixed and dry, three or four shades lighter in tone than when they came out of the gold; from a cold grey to a warm brown afterwards: the second two sheets would be only, perhaps, one shade different, whereas all afterwards would be the same tone when dry as when they left the gold. This is not so much a difficulty to the professional printer, as he has only to begin with the "*Browns*," and end with the "*Greys*," but must be a trouble to those who only wish to produce one tone of picture, and that a dark one; and is in all cases a loss of gold, which is hardly worth the trouble of extricating from so large an amount of hypo. It gets precipitated along with the silver, by an alkaline sulphuret, by those who save their waste solutions. It was for the purpose of preventing this loss, and not to assist by toning by sulphuration, that Mr. Hardwich recommended using the hypo a second time, using chalk or common soda to keep it from acidity, as he said it improved the colour—rather a dangerous thing to say, as it looks ugly, and might have a suspicious meaning attached to it; it should rather have been, as it prevents the colour from deterioration. Most photographers, however, prefer now always to use fresh solutions; there is, therefore, no way of proceeding, but overturning the first proofs if darker tones are preferred. Perhaps Mr. Dawson, if not too much engaged with his avocations, will kindly reply to the above remarks, whether I have stated what I believe to be his calculations are correct, and also give us any further benefit of his experience in the above most important considerations.—I am, dear sir, yours sincerely,

Francis G. Eliot, Photographer.

Elm Grove, Peckham, S.E.

SHARP FOCUSSING.

Dear Sir,—I have adopted a simple and exact method to ascertain that my dark slides are correct with the focussing screen, which I think is much preferable to using a ground or collodionized glass in the dark slide in place of the screen, as in this case, not only is the eye a treacherous guide as to the image being equally distinct on the two glasses; but after having focussed the image as sharp as possible on the screen, you are not well able to judge, on substituting the dark slide, whether it exhibits the *sharpest possible* picture, without moving the lenses to and fro, and so throwing them out of the position they occupied in giving the image on the screen.

My plan is as follows:—

Remove the back portion of the camera (if sliding body) together with the screen. Upon the ground glass erect perpendicularly a strip of other ground glass, or a piece of wood, and place across the camera a glass plate or other rigid and level substance, and bring it in contact with the perpendicular strip; upon this, with the cross piece as a ruler, make a pencil mark: now remove the screen and substitute the dark slide (containing a plate), and repeat the operation.

The distance between the two pencil lines thus made will show how much, and in what direction the focussing screen requires correction: if the lines be coincident, the arrangement is correct.

If the camera be not a sliding one, the same method may be adopted by removing the lenses.

It is necessary to guard against using any pressure upon the perpendicular, as the spring which holds the plate will give way unless a firmer support be placed behind the slide. —I am, dear sir, yours faithfully, Focus.

Kilburn, N.W., July 27th, 1861.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

Dear Sir,—I am desired by the referees of the Amateur Photographic Association to state (since from the number of members there is no longer a doubt of its success):—

1. That the Amateur Photographic Association is now fully established.

2. That all negatives for this year should be sent in not later than Nov. 1, and as much earlier as possible.

3. That the secretary is prepared to negotiate exchanges for all members who may desire it, which exchanges will, as a matter of course, have no reference to the prints to be selected by each member.

4. That the adjudication of prizes will take place at the close of this year, or the beginning of next.—I am, dear sir, very truly yours,

A. J. Melhuish, Hon. Sec.

July, 1861.

Talk in the Studio.

South London Photographic Society.—The August open-air meeting of the South London Photographic Society will be held on Saturday the 9th instant, at Beddington Park. Members will meet at the West Croydon station at 2 p.m., and thence adjourn to the park.

Penny Photographs.—Photographic portraits of public characters, generally reproductions of engravings, are becoming regular articles of street commerce. A paper print of the ninth size (2½ in. by 2 in.) with glass and preserver, all being sold for one penny!

Congress of Artists.—There is to be a grand congress of artists of all nations at Antwerp next month. The gentlemen chosen by the Royal Academy, to represent English art are Sir Edwin Landseer, Messrs. David Roberts, E. M. Ward, Doo, and Westmacott.

The Beautiful.—Never lose an opportunity of seeing anything beautiful. Beauty is God's handwriting, a wayside sacrament; welcome it in every fair face, every fair sky, every fair flower, and thank Him for it, the fountain of all loveliness; and drink it in simply and earnestly, with all your eyes; 'tis a charmed draught, a cup of blessing.

Canadian Photographs.—We have recently received a parcel of very fine card portraits from Messrs. Nottman, of Montreal. Amongst these are some portraits we recognize, as that of Sir William Williams, of Kars, and others. As photographs, the pictures are very fine, being at once soft and brilliant: they possess at the same time a high artistic character, the arrangement of position, accessories, lighting, &c., all conducing to a satisfactory pictorial result.

The Comet.—Mr. John A. Whipple, of Boston, whose photrographs of the moon and stars and Donati's comet have excited attention, reports that the photographic power of light from the comet is very feeble, hardly making an impression on his most sensitive preparations. Compared with that of the moon, or fixed stars even of the third or fourth magnitude, it is, photographically speaking, *not one thousandth part as brilliant.*

Photography in Paris.—A recent Paris census gives no less than 33,000 persons as connected with the production of photographs and photographic materials! If photography deprived tens of persons in the shape of inferior miniature painters of a subsistence, it has manifestly provided employment and incomes for thousands of persons in their places.

Photographs at South Kensington Museum.—A recent report of the Science and Art Department, at South Kensington, informs us, that during the last year the demand for photographs far exceeds the supply. Since the opening of the offices, in October, 1859, to December, 1860, 15,584 have been issued. Negatives have been made from the *Liber Studiorum* of Turner; and, by way of experiment, to ascertain how far the assistance of private photographers can be employed in printing and publishing photographs, some have been invited to purchase these negatives at cost price: one established firm has undertaken to produce these, the Department reserving the liberty to sell other negatives of the same work, if the public call for better or cheaper impressions. The firm referred to is Messrs. Cundall and Downes, and from what we have seen of their copies of the *Liber Studiorum* we venture to assert that better copies or at a cheaper rate cannot possibly be desired. We hope shortly to have a more extended notice of these valuable reproductions

To Correspondents.

F. K.—The India paper effect to which you refer in mounts for photographs is sometimes really India paper, and in other cases a tint produced by lithography. We cannot tell you where such mounts are to be procured

M. C. C.—The achromatic stereoscopes to which we referred, cost, we believe, about £2 each. We prefer whole lenses to prisms.

W.—So far as our own experience goes, we should say No. 3. Add, say six minims of strong ammonia, and two grains of citric acid. A longer exposure is not required. We prefer the plate thoroughly well washed before applying the albumen. If working wet collodion in the field, it is not absolutely necessary to fix immediately after development. If the plate be properly washed after development, the fixing may be delayed to a convenient season. The chief difficulty to be guarded against is loosening of the film from the repeated operations of drying and rewetting.

. Gordon.—Franc's has two kinds of rolling presse , one acting as a kind of burnisher, and the other by acual rolling presser . The latter is, we believe, considered most efficient. Marion has also a rolling press, of which we have heard good accounts. The prints, after mounting, should be quite dry, before being rolled. We should have pleasure in seeing the Indian stereographs to which you refer.

F. S.—The means of producing intense negatives by iron development depends on several conditions, one of the most important of which is the use of a collodion with sufficient tendency to density, and a strong bath in good order. We shall have an article on this subject shortly, probably next week, as it cannot be treated fully here.

Alpha.—All single view lenses give curved marginal lines; but if the lines converge, as you state, towards the top of the picture, that arises from the camera being tilted. In taking a building, no matter what lens you use, it is imperative, if you would prevent this distortion, that the plane of delineation, or, in other words, the sensitive plate, be quite parallel to the building. In taking a landscape, including many objects, we prefer focussing for the foreground, unless it happen that some other object be of vital importance; but in taking a building it is necessary to use a little judgment and select that point for focussing which gives the best general result. In many cases the most interesting architectural point of the building should be chosen for focussing, but each individual case will require judgment, as no rule can be given. The triple lens is the best for giving perfectly straight lines and freedom from distortion.

F. E. G.—A bath made with pure re-crystallized nitrate of silver, 35 grains to the ounce, with the smallest possible proportion of acid which will make it work satisfactorily; a bromo-iodized collodion, and iron developer, are all required for instantaneous work in a good light. The bath made as you describe it, will answer admirably, we have no doubt, with the excellent lenses you have procured.

F. S. Beatty.—We forwarded the letter as desired. We shall have pleasure in receiving the illustration referred to, and hearing more about your process.

T. S. Swatridge.—The specimen forwarded has many points of excellence, being a soft and artistic picture. The head is scarcely quite sharp, and the drapery might have been a little better illuminated and rounder; but, as a whole, the picture is very good, and displays artistic feeling. The printing also is very good, although a little more broken form of vignette would have been an improvement. A vignette of regular oval shape is somewhat formal. We shall be glad to hear of your process.

W. A. Y.—1. In adding oxide of silver to a bath containing nitric acid and acetic acid, the nitric acid will act on the oxide first and form nitrate of silver, and if you could just add sufficient to neutralize the nitric acid and no more, acetate of silver would not be formed, but as you do not know the exact amount of nitric acid present, it is almost certain that acetate of silver will be formed in neutralizing the bath. 2. If you add a very dilute solution of an alkali a drop at a time, and test carefully between each addition, the nitric acid being neutralized first, you may, possibly, avoid the formation of acetate of silver. 3. Nitric acid may be liberated in a bath in the regular process of working, by the use of a collodion containing much free iodine, as then the nitric acid is set free from the nitrate of silver, by the formation of iodide of silver, and no other base supplied to combine with it. 4. When you have once got excess of acetic acid into a bath it is very difficult to eliminate, the best plan is to neutralize it with oxide of silver, and then reduce the temperature of the solution as low as possible, which will cause the excess of acetate of silver to crystallize, and it may then be filtered out. Or dilute the bath with an equal bulk of distilled water, which will precipitate the excess of acetate, filter, and then add sufficient silver to make the solution the proper strength. 5. To make oxide of silver add a solution of caustic potash to a solution of nitrate of silver until it is all thrown down as a brown precipitate, which is oxide of silver; wash well and it is ready for use. 6. Add the oxide of silver in excess and then filter. 7. We do not like old collodion baths saturated with iodide of silver for printing purposes. To remove the iodide proceed as we have described for the acetate. When an old bath fails to give good pictures renew it by adding new solution of full strength.

R. Keene.—We have communicated with Mr. White who informs us that he gave the negative to the sculptor, Mr. Thorneycroft, from whom, or from Spooner, Southampton Street, Strand, it is possible a print might be obtained.

E. N. C.—The mottled appearance in your print is from imperfect fixation. You have used a hypo bath either much too weak, or exhausted from long use. The consequence is, the formation of insoluble hyposulphite of silver, which nothing can remove from the picture. Use a fresh solution of hypo, one ounce to four of water. We are always glad to assist our readers, but we cannot accept any remuneration for our advice.

J. W. S.—The Fothergill process is the simplest dry process. See the Photographic News Almanac for a complete epitome of all the dry processes.

E. H. B.—The only modification your method of manipulating seems to require is more careful washing before immersing in the hypo. The fault appears to be in the paper, and we regret to say is at present of very common occurrence. We were surprised at the statement to which you refer, about a quarter of an hour in the hypo we have always found sufficient in our own practice.

A Distressed Photographer.—A wooden bath coated well with shellac might doubtless answer for the silver solution. A better plan still, is that adopted by Mr. Francis, of lining wooden baths with thin sheet india-rubber. We have one in use at present, and intend to report shortly. 2. A bromide in the collodion shortens the exposure where iron development is used. 3. Dr. Hill Norris has two dry processes, one of which has has been published; the other, the rapid one, is a secret. We have for years used kaolin to decolourize the nitrate bath. Our plan is to place a little kaolin in the funnel inside the bibulous paper, and thus filter through each time in returning the solution from the dish to the stock bottle. When pouring into the dish for use, we never drain the bottle, but leave any sediment undisturbed; we also remove any floating scum with a strip of paper, and thus have no sheets wasted. 4. The coagulation of the albumen has been proposed and would probably be beneficial. See letter of our Paris correspondent in the present number. 5. Mr. Fry's plan is to use common water: he finds it successful. 6. Holes in an unvarnished negative are certain to occur from contact with the paper in the pressure frame. We shall be glad to hear of your results with the Rev J. Lawson Sisson's process.

Photo Student.—We think it is not desirable to insert your letter as we have no desire to open our pages to recriminatory correspondence, or emulate some of our contemporaries in becoming the vehicle of offensive personalities. We cannot tell you where you may enter on "a course of Billingsgate," in order to reply efficiently; nor can we recommend you to enter upon the study. In any case you cannot "exercise" in the pages of the News.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 153.—*August* 9, 1861.

FREE IODINE IN THE SILVER BATH.

Have any of our readers tried the addition of free iodine to the silver bath as proposed by M. l'Abbé Laborde?* We have tried it, and we must confess to disappointment in the result. It will be remembered that the Abbé premises his announcement by the statement of a case which every photographer is too familiar with: namely, that whilst to secure the highest conditions of sensitiveness a neutral silver bath is desirable, that neutrality generally has a tendency to bring with it another evil, the disposition in the shadows, or *reserves* as he calls them, to veil or fog. To get rid of this, it has been generally found necessary to give the bath a slightly acid reaction, and with this amount of acidity, added, there is often a slight amount of sensibility lost. To meet the difficulty here involved the Abbé announced that the addition of iodine, to the bath already saturated with iodide of silver, was a complete remedy for this tendency to fogging, whilst it in no degree diminished the sensitiveness of the film, or caused any acid reaction. The first statement of this case will, to the photographer at all aware of the reactions which take place in the processes he works, appear to involve a contradiction. He is aware that on immersing a plate coated with iodized collodion, into a bath of nitrate of silver, a process termed double decomposition takes place, in virtue of the greater affinity existing between iodine and silver, than between these elements and the bodies with which at the outset of the process they are associated. Thus the nitrate of silver is decomposed, and the silver combines with the iodine, whilst the base with which the iodine is associated, say potassium, combines with the nitric acid and oxygen liberated by the decomposition of the nitrate of silver, and forms nitrate of potash. If, however, free iodine be brought in contact with a solution of nitrate of silver, iodide of silver is formed, and nitric acid set free in the solution, there being no base present with which it can combine. Photographers are aware of the value of free iodine in a collodion intended for positives, which causes it to give clear shadows and silvery whites. This is due to the liberation in the nitrate bath of a minute trace of nitric acid, the well known operation of which is to produce such results.

M. Laborde is well aware of this, and to account for the novel circumstance which he announces, remarks—"We cannot apply the ordinary laws of chemistry to this fact; or, rather, we must search deeper into these laws to find an explanation of it. For every chemist will think that iodine in contact with nitrate of silver will remove the silver, and set some nitric acid free; this acid would then act like most other acids, in opposing the reduction of the silver upon the reserves. But it is found that the prolonged contact of iodine with the silver bath, well saturated with iodide of silver, does not cause it to lose its neutrality; the nitrate bath containing iodine may be heated nearly to ebullition without manifesting subsequently any acidity."

In order to test this valuable quality we made a new nitrate bath, thirty-five grains to the ounce, of very pure neutral nitrate of silver: to this we added iodide of sodium in order to saturate with iodide of silver. We then filtered and tried a plate. The bath on being tested was found neutral, and worked quickly, clean, and well, with the exception of giving a slight veil to the shadows. We then added a little iodine, using for convenience a few drops of a concentrated tincture of iodine. Another plate was tried, and the shadows were at once found clearer; but the deposit was observed to possess a much more silvery whiteness viewed by reflected light, and a tendency to greyness when viewed by transmitted light. The plate taken first was then compared with this, and found to be much more of a brown tint by reflected light, and a reddish brown by transmitted light. The change was strikingly suggestive of the action of nitric acid, and on again testing the bath with blue litmus paper, a faint acid reaction became manifest.

Unwilling, on slight evidence, to come to a conclusion opposed to that announced by an authority so eminent as the Abbé Laborde, we conceived the possibility of the solution not having been perfectly saturated with iodide of silver to commence with, a point on which the Abbé had laid some stress.

Taking, therefore, a portion of the bath, we added more iodide of sodium until it was in considerable excess. We then, having first neutralised the solution with oxide of silver, added, not tincture of iodine, but a few grains of iodine. Blue litmus paper remained for some time unchanged, but gradually became reddened, commencing at a point where it was in absolute contact with a portion of the iodide.

Still willing to attribute the result to some failure in the conditions laid down, we read M. Laborde's statement of the case again, and observed that he described a slight acid reaction as sometimes the consequence of atmospheric action, independent of the iodine, and we began again, this time using fresh preparations. Instead of using iodide of sodium, we used iodide of potassium, adding it in excess to the silver solution, and allowing it to stand for twenty-four hours, so that it might get thoroughly saturated with iodide of silver. We procured a fresh and very fine sample of iodine, the one previously used having stood in our laboratory ever since the days when it was needed for daguerreotype purposes, and might, possibly, not be in the best condition. We now followed the Abbé's instructions carefully as to quantity, and added one part of the iodine to two hundred parts of the solution, and instead of allowing it to stand in an open vessel as before, it was placed in a stoppered bottle. Very slowly the blue litmus paper, which had remained in the solution before the addition of the iodine for half an hour without change, now began to assume a lavender and then a pink hue; as before, first showing the change where a particle of the iodine touched it,

The neutrality of the solution was in all cases carefully ascertained previous to the addition of iodine, and, where it was doubtful, placed beyond question by the addition of oxide of silver. We have one other experiment to record, which slightly differs in conditions and results from those just stated. In order to vary the mode of examination, we took an ounce of an old silver bath in good working order, but which, having been in use for three or four years, was, of course, saturated with iodide of silver, and unquestionably contained free nitric acid. This was neutralised with oxide of silver, and a few grains of iodine added. In this case no apparent change took place; the iodine remained unaltered, and blue litmus paper retained its colour for a great part of an hour, when the solution was removed. In the other cases a gradual agregation of yellow particles of iodide of silver formed round the fragments of iodine, contemporaneously with the change of colour in the litmus paper.

It will be remembered that our German correspondent, Herr Liesegang, an intelligent and careful experimentalist,

* Vide letter of our Paris Correspondent in the number for June 28th, p. 308.

stated in his communication a few weeks ago, that he had tried M. Laborde's suggestion with perfect success. That the shadows of pictures produced in a bath so treated were remarkably clean, and the collodion positives very brilliant in tone. He does not state, however, whether he actually tested for acidity. If he did not, the results obtained are just those consistent with the presence of nitric acid, the fine tone of the collodion positives essentially pointing in that direction.

In conclusion we merely assert that in our hands, and in the series of experiments recorded, whilst the end was gained, it appeared to be by the liberation of a very minute trace of nitric acid, which, whilst it gave clearness to the shadows, did not appreciably interfere with the sensitive condition of the bath. We would be far from asserting, however, that under other conditions, not yet precisely indicated, the exact results indicated by M. Laborde would not take place. It is only fair to assume that so eminent an authority is precise in stating the case as it presented itself in his hands, but that some conditions which escaped his attention are necessary to secure the same result, and which in our experiments with a new bath—the case where they would really be needed—were absent. We shall be glad to hear the result of other independent experiments.

VALEDICTORY.

The private life of public men is not public property: yet, in so far as the purposes of the private life affect public relations, they become, very naturally, matters of general interest. The retirement from all public connection with photography, on the part of one who has so long held a foremost position, as an expositor and authority, in regard to all its scientific subtleties, may justly be regarded as a matter of legitimate interest amongst photographers at large. Those who had the privilege of possessing the friendship of Mr. Hardwich have known for some months past that his labours and public connection with photography had ceased, and that his future career would probably be in the church. To a gentleman of a disposition so pre-eminently modest and retiring, we conceived that any public mention of these facts could only be painful, and we have abstained from all reference to the subject. As two of our contemporaries have now alluded to the matter, we can have no further delicacy in informing our readers of a fact which will possess to them a regretful interest, and in seizing the opportunity of expressing our high sense of the obligation the art and its votaries owe to the labours of the retiring *savan*.

In a letter before us, addressed to a friend, a couple of months ago, Mr. Hardwich states that he is now stationed in a large mining and manufacturing district assisting the clergyman to visit and look after his people, and that if his health will permit he will shortly enter into holy orders with a view to "spending the remainder of his life in preaching the gospel." He says, "I have long wished to do this, but not until lately was the way opened up before me. At present I am visiting the sick, prescribing for some, reading to others, and occasionally giving addresses and cottage lectures to the people. Photography, as you may imagine, is at a standstill." He concludes an interesting letter by stating that he shall always feel interested in the progress of the art, and by sending kind remembrances to ourselves and other photographic friends.

However much we may regret the loss to photography of one who, by education and habit, had rendered himself almost necessary to its scientific progress, it is not a matter which permits a word of comment. If what is generally regarded, at least in a worldly sense, as honour and profit had been his aim, we believe it was to have been found in photography. But motives of a higher order have unquestionably dictated this step, and we cannot but regard it as somewhat derogatory to the man, and altogether misappreciative of his motives, to suppose that the rewards photography has to offer were insufficient to retain him as one of its chief expositors. A man so conscientious cannot fail to be useful, however, whatever may be the field of his labour. We have reason to believe that in the mining districts of Durham he will find a sufficient number of earnest minds to render it a not altogether ungenial sphere, and we cordially wish him good speed in his new vocation.

Science is already largely indebted to men in the church for many of its most valuable contributions; and it is but fair, perhaps, that on some occasions an interchange of good offices should thus be made. And as the pursuit of science is not in any way incompatible with the ministry of the gospel, perhaps we may hope, that at some time other "Recreations of a Country Parson" than those which have been recently delighting the reading world, may appear for the gratification and instruction of photographers.

A correspondent in a contemporary has suggested the propriety of some formal recognition of the value of Mr. Hardwich's services amongst us. There are few, we believe, who would hesitate to acknowledge and recognise those services; but we cannot but think that the necessary publicity of such a recognition would, under the circumstances, be wholly, and without mitigation, a source of pain to the gentleman to whom it would be intended as a compliment.

Notes and Jottings.

No. 9.

Photolithography: A Suggestion.—Intensifying Dry Plates with Bichloride of Mercury and Iodide of Potassium.

Photolithography continues to claim some degree of attention from time to time. So far as regards the reproduction of subjects without half-tone—that is, half-tone as photographically understood—some specimens we have seen from two or three sources have little or nothing to be desired. Still, however, we hope in time to attain some means of approaching somewhat nearly the gradations of the photographic print. At present, even a rough approximation to the desired end can hardly be said to have been got. The results of experiments are, however, "promising," and therefore we shall continue to hear more on this point for some time yet to come.

To those who may have the means of conducting experiments in this direction, we offer a hint which we do not remember to have seen previously published.

Lithographers are in the habit of using gum arabic to "stop out" on the stone. Wherever the gum touches, although all the surface be afterwards covered with grease, those portions will print white. Now if we take a paper coated with bichromate of potash and gum arabic, and expose it under a negative, we get the well-known effect of insolubility in the exposed portions, and solubility in those unexposed. Placing the print thus obtained, face downwards, on a prepared stone, slightly damping the back, and passing through the press, the soluble parts, otherwise the whites of the picture, are transferred.

We thus get a negative copy of the photograph on the stone. When dry, the whole surface may be covered with grease, after which the lithographer may proceed in the usual manner.

At present this is only a crude hint, but we may have more to say on the matter shortly. Any suggestions, however, on this important subject will not, in one sense, be thought entirely without value.

In our last "Jotting," when speaking of intensifying by means of bichloride of mercury and iodide of potassium, we promised to say something on the application of the process to dry plates. This promise we now redeem. The action of the solutions on dry plates will be found far more energetic than on wet. This to a great extent is, perhaps, owing to the organic state of the film. The solutions should, therefore, be largely diluted, especially the bichloride of mercury, If this latter be allowed to act too strongly, the image will quickly whiten, in which case the resulting negative will be yellow, whereas we prefer its being a yellowish brown. The use, however, of ammonia in the iodide solution will bring the colour back to the desired tint.

Cyanide, used in fixing, should not contain much silver in solution, or, at all events, the film should be well washed after its application; for if any free silver remains in the pores, it may be thrown down as an iodide, and thus a slight veil cast over the negative.

In other respects proceed as with wet plates.

M. Hannaford.

Scientific Gossip.

We have received several more samples of glass from various correspondents, who desire to know the results of an examination of the same in the spectroscope. If these pieces are to be considered as a fair illustration of the sort of protecting medium behind which photographers are in the habit of working, they certainly show that more than half the failures should be attributed to the passage of chemically acting rays into the dark room; the only reason why good pictures are ever taken by some amateurs and professionals being, that in addition to the coloured glass, they cover the window with two, three, and in one case even four thicknesses of yellow calico. This occasions such darkness in the room that considerable quantities of actinic rays might pass through the screens without being sufficient to affect the sensitive plate. In fact, the human eye is so far superior in sensitiveness to the most delicate collodion film, that we have, on more than one occasion, sensitised and developed collodion pictures in a room illuminated with ordinary daylight; no colouring medium whatever being employed; the shutters and curtains of the window being so nearly closed that only sufficient light was allowed to enter to enable us to see what was going on in the distant corner where we had planted the bath and developing tray. by taking care to keep the plate overshadowed as much as possible, and only examining it once or twice towards the end of the developing process, very excellent pictures were obtained, perfectly free from fog or stains of any kind.

It is therefore evident that by reducing the light in the dark room to the least amount with which it is possible to work, the perfect exclusion of actinic light by the yellow glass or fabric, is a matter of very little importance. This, however, is a most unsatisfactory way of working, and since the information which we are now in process of detailing in these columns will enable anyone to work in almost as bright a light as they may desire, we do not imagine that many of our readers will continue groping about in "darkness visible," manipulating more by touch than by sight.

We will adopt the same arrangement in describing the glasses, as we used in our last "Scientific Gossip." Any references which may be necessary will be made to the diagram there given.

10, F. W.—This specimen of glass is of a green colour, apparently coloured with copper. All the red end of the spectrum is cut off below C, but apparently very little of the blue end is obliterated, although it is much weakened. The green rays are apparently seen to encroach considerably on the yellow and blue parts of the spectrum. This glass, it will be evident, is of scarcely any value for photographic purposes.

11, Dr. H. (Ireland).—This is a flashed glass of a deep orange colour. It exercises a strong action on the spectrum, entirely cutting it off above E, and partially obscuring it from D to E. The whole of the green, blue, indigo, violet, and invisible rays are therefore intercepted, and no danger need be apprehended when this glass is used to illuminate the dark room, however strong the light may appear which passes through it.

This glass is identical in tint with a piece which has been forwarded to us by Mr. Crookes as a specimen of the colour which he has been, for some years, in the habit of using for photographic and experimental purposes. He describes it as being quite opaque to all rays above E, transmitting only the orange, yellow, and red rays; the transmitted light being quite free from action on a collodion plate, under all circumstances which could happen in the practice of photography. This piece of glass is at present at our office, where it is open to the inspection of anyone who may wish to examine it.

12, L. D.—A brilliant lemon-yellow glass. A very decided effect is produced by this glass upon the violet end of the spectrum, cutting the whole of it off above G. As, however, the indigo and blue are left in scarcely diminished strength, the glass is unfit for photographic purposes.

The yellow, orange, and brown glasses, which we have hitherto examined, may be divided into three classes, according to the colouring matter employed in their preparation. Class I. consists of those coloured by iron; Class II. those in which carbon is employed to give the colour; and Class III. in which the colouring agent is silver in the form of silicate of the oxide. The first and second classes are worthless, except in several thicknesses, numbers 6, 7, and 8 being of this kind. The third class, of which No. 11 is an example, coloured with silver, is the only kind which should be employed for photographic purposes, and if our glass manufacturers would but devote a little attention to this subject, a very perfect article would soon be able to be obtained by every photographer. As at present made, silver-coloured glass is mostly flashed, *i.e.* coloured only on the surface, the bulk of the glass being colourless, and the stain being produced by an excessively thin film of a very dark-coloured glass on one side only. This is wrong in principle, although it may frequently act well in practice. According to this plan of colouring the glass, it it impossible to regulate the thickness of the colorific film, and, as a natural consequence, no two sheets are alike in colour. Another objection is, that any chip or scratch on the coloured side removes the colouring matter and allows white light to pass through. The same piece of glass is also liable to vary considerably in colour; a sheet six inches square frequently being several shades darker at one end than at the other. The proper plan would be to make the sheets of glass from a pot of "metal" which has been previously coloured to the proper intensity throughout its mass, by addition of the requisite quantity of silicate of silver: this could then be worked into sheet or plate glass of different thicknesses, and of any desired tint for the use of photographers. It is surprising what a strong opacity to the chemical rays, is produced by the slightest trace of silver in glass. It is owing to this cause that some lenses are so much slower than others. In order to obtain the glass of great density, which is necessary for grinding the curves for *rapidly-acting* lenses, the maker is obliged to add a considerable quantity of lead to the material of which the glass is made (some of Faraday's "heavy glass" actually contains half its bulk of metallic lead). Now it is a curious circumstance that lead and silver are almost always associated together in nature, all commercial lead, unless specially purified, containing certain quantities of the precious metal, even after it has gone through the separating by Pattinson's beautiful process; and when so large a proportion of lead is added to the optical glass, the silver which is introduced at the same time becomes sufficient to communicate a decided opacity to the higher, chemically acting, invisible rays. It is more than probable, if some of our large glass-melters were to take the precaution of only employing for their optical glass, lead chemically purified from every trace of silver, that photographic lenses could be made to act far more rapidly than they do at present; for, as now made, there is scarcely a sample of optical glass without some silver in it.

Another fact connected with this silver-coloured, flashed glass may be worth mentioning. If the surface be examined minutely, by transmitted light, with a magnifying glass, it will be seen to present a decided mottled appearance, looking as if the colouring matter had been laid on in powder, and had then been fused into the sheet of glass. In default of an examination by the spectroscope this appearance may be used to ascertain whether a piece of glass has been coloured by silver or not. If it present this peculiar appearance, it may be generally taken for granted that silver is the colouring matter employed, and then the photographer need only select the darkest piece he can find.

This connection between the sensitiveness of silver compounds to the actinic rays and the opacity of silver-glass to the same kind of light is more than a mere coincidence.

NEW VARNISHES.

We have received from Mr. Henry Rigge two samples of varnish possessing somewhat novel characteristics, and which promise, if all claimed for them prove true, to be very useful to photographers. They present themselves at the outset with the novel character of being spirit varnishes, but requiring no heat, prior to or after their application to the collodion film. Benzole and chloroform varnishes, it is well known, may be applied without heat, but the gums soluble in these fluids have been generally of the soft and friable character, which have rendered them unsuitable for the protection of negatives. Spirit varnishes have generally contained harder gums, and have been for this reason preferred as negative varnishes; but they have always required the plate to be warmed previous to their application, and a sufficient amount of heat during their drying has been necessary, to prevent the varnish from chilling. This, during the summer months, is frequently a serious inconvenience, as there is not generally a fire accessible, and the heat of a flame, whether from gas or a spirit lamp, is not well suited for the purpose, a red, even glow answering best. A spirit varnish, then, which claims to be as hard as other spirit varnishes, and is able to dispense with heat during its application, is at least worthy of attention.

The samples consist of a negative and a positive varnish, both of which when poured on glass dry perfectly brilliant without heat, and give a very beautiful even textureless layer of gum. In a short time they are set, and appear, to the touch of the finger-nail, perfectly hard. Our experiments with them have necessarily been limited, but we were scarcely so well satisfied with the results of our trial on the collodion film. We varnished a negative and allowed it to dry without heat, a very fine even film of varnish resulting. Intending, however, to put it to the most trying test, we placed a piece of sensitive paper not perfectly dessicated, but still slightly moist, so that in the pressure-frame it was pressed into that extremely firm contact which its limp moist condition rendered easy to accomplish. It was then placed in the full blaze of a mid-day sun, and when the outer glass of the pressure-frame had become very hot the print was removed. The varnish had certainly under this treatment become somewhat tacky, and the print pulled portions of the film away with it. These are conditions which we should scarcely apply in general printing operations; but in experiments of this kind we prefer to try extreme tests. The same varnish when applied with heat, appears to become harder, and less subject to subsequent tackiness under the influence of heat.

The positive varnish gives a beautiful surface to which powder colours adhere tolerably well. In experimenting with it we must mention one curious circumstance of a kind we never before met with. A collodion positive which had stood in a box, unvarnished, for the last four or five years, was varnished with this positive varnish, when the most singular result followed; it began to be covered with white arborescent tracings, which quickly ran into each other, and finally, in a few minutes, the whole plate assumed a beautiful opalescent appearance, altogether unlike the granular effect produced by the chilling of a spirit varnish. As we have coated several other collodion positives from the same bottle, and in the same manner, with perfect success, and obtained a beautiful transparent surface, it would scarcely be fair to regard it as the result of any imperfection in the varnish. It would rather suggest the possible existence of some amount of decomposition in the collodion, which had been kept for many years unprotected, and which was easily acted on by the varnish. We mention the circumstance chiefly because of its unusual character. A subsequent application of the same varnish and the aid of heat restored the picture to its proper condition.

Mr. H. N. Brunelliere, who is, we believe, the inventor of the varnishes, thus writes on the subject:—

"Both varnishes are made with one of the hardest gums known, rendered still harder, and pliable as gelatine, by a complicated chemical process, as you may see by the tenuity, transparency, and pliability of the films sent as samples.

"They are both of the same nature, the positive holding less gum in solution, and a small portion of another gum adopted to take powder colours.

"They possess the advantage of drying bright, without heat, and, therefore, are found very useful when artificial heat cannot easily be procured, with the facility of heating the film at any time afterwards, after printing, if you like, and get it as hard as any varnish known.

"The negative may be used in mounting micrographs, or microscopic objects, without the aid of heat, drying rapidly on any very cold material, as you will see by the pieces of glass cemented with it.

"Benzole varnish is found useless comparatively, either for its offensive smell, or for the softness and brittleness of the gums employed in its manufacture, to say nothing of the bad colour it imparts to positives when the proper amount of gum has been used so as to make it dry bright."

Some films, or layers of the varnish, very similar to very thin gelatine, were forwarded to us, which showed that the gums possess considerable toughness. The negative varnish appears also likely to answer the purpose of a cement for glass in some cases, as the two pieces of glass referred to illustrate, being joined so firmly that we cannot separate them.

As we said before, a varnish coming with such claims is at least worth a trial by those whom it may concern. In making trial at any time of a new varnish for negatives, we would suggest that it should be done on one of little value, as good negatives should not be subjected to any unnecessary risk.

WASHED COLLODION PLATES.

BY M. A. GAUDIN.

Some years ago I asserted that the presence of nitrate of silver upon the collodioned plate during exposure was quite useless, and that, consequently, it might be entirely removed from the plate with the advantage of obviating many important inconveniences. Since then, in consequence of a hasty experiment I made upon an opinion expressed by Mr. Thomas Sutton, I declared myself in error, and that, doubtless, my first experiment had been badly performed: but I formed the project of attesting a fact announced by Mr. Sutton, viz.:—that wet collodion plates when washed never yield strong negatives, whatever the amount of exposure. This I concluded was due to a faulty development: the researches I made on this point have led to certain results of the highest importance, which cannot fail to immediately realize a great improvement in the employment of collodion.

Every photographer must have experienced great annoyance in operating with wet collodion in the ordinary manner. He is obliged to expose the sensitised plate with as little delay as possible, being limited to a few minutes after the plate is removed from the nitrate bath; if the exposure be delayed, especially in hot weather, failure is the result; and even when the operation has been prompt, the plate is frequently stained by contact with the fingers or the slide. This inconvenience need exist no longer, for a wet collodioned plate when washed of its nitrate *is quite as sensitive* as when it is covered with nitrate; it is only necessary to know what mode of development to pursue.

To satisfy myself of the correctness of the principle, I repeated my old experiment, but this time on a long plate adapted to a binocular stereoscopic camera, which removed every chance of error. After sensitizing a plate, and allowing it to drain for a few minutes, I washed one half of it in a vessel full of river water; then, after exposure, I replaced it in the nitrate bath. In proceeding to develop the plate, the unwashed portion gave a very pure image, while the washed portion was veiled; but, what was most important, the latter had as much reduced silver upon it as the former; thence I concluded, that washed plates only required for their development a developer more strongly acidulated. In fact, washed plates developed with a reducing agent, which operated slowly, give pictures of the first quality, while their sensibility is exactly the same: only it is necessary to observe certain conditions which obviate the effects of the washing.

Washed collodion-plates are not only quite as sensitive, when properly developed, but we at once perceive that this washing is a means of obtaining an unusual degree of sensibility, as we can introduce into the washing-water a host of reagents capable of penetrating the sensitive film, and thus concur in the rapidity of the exposure.

It has been objected that my plan of washing the plate in plenty of water, without afterwards rinsing in distilled water, always leaves some nitrate on the film: and this is true; but in the present case, the object is not to wash the plates, and then to dry them completely, but rather to suggest a practical method of operating with wet collodion plates kept for several hours, which is all the latitude required in most cases.

By washing in plenty of water, not followed by a rinsing, the water remaining upon the plate contains at the most, a thousandth part of nitrate of silver. For the same vessel of water will serve for a whole day's operations, and if this thousandth part is considered necessary to exposure, I grant it; the fact is, that *it suffices.* This minute quantity acts as efficaciously as a quantity a hundred times greater, but without the inconveniences of the latter, and moreover this method of washing is more practical.

Thus, then, in washing sensitized plates in a large earthen or glass dish full of river water, we leave upon the plates only a ten-thousandth part of nitrate at the beginning, and a thousandth after washing about forty plates. It is well understood that in employing ordinary water, before washing the first plate, a little of the silver bath must be added to it, to neutralize the salts it may happen to contain; besides this water must be acidulated by the addition of one per cent. of acetic acid.

In washing the plates, it is evident that we introduce into the substance of the sensitized film, in lieu of nitrate of 10 per cent., a nitrate at least a hundred times weaker; therefore, before proceeding to developing, it is necessary to restore the balance. This is realized by putting the plate into the bath; but its stay in it must not be momentary, as usually practised, it must be left in the bath several minutes, and proceeded with exactly as with a plate being sensitized. After this, it is left to drain for a minute, before proceeding to development.

When a washed plate has remained only a quarter of an hour in the air before exposure, it is useless to return it to the bath; we pour on its surface the developer, to which nitrate of silver of the strength of 3 per cent, is added, the quantity of developer being very small, and when the image appears, some *pure* developer is added.

Developers with an iron base, cannot be employed except with plates returned to the bath, and always with a large proportion of acid. I employ a special pyrogallic-acid developer, which yields very pure positives, with brilliant whites, or negatives of extraordinary intensity, according to the length of exposure.

By washing the plates we completely avoid the stains arising from the frames. When the developer with nitrate of silver is poured on the film it spreads quite readily of itself, and as it acts slowly, the image is developed with limpidity.

I have also made an experiment with a view of obtaining still greater sensibility by modifying the washing water, and I have succeeded beyond my hopes.

Besides acetic acid I have added to the washing water a small quantity of tannin (15 grains to 10,000), and after sensitizing a stereoscopic plate, I washed two-thirds of it; after exposure, and returning it to the bath, developing produced upon the washed portion a negative twice as intense as that portion which had not been washed, but the strongest negative was a little fogged, although good to print from; I believe, therefore, that the addition of tannin is advantageous, but the quantity must not exceed half the quantity indicated above.

THE THEORY OF THE PRIMARY COLOURS.

An interesting lecture on this subject was recently delivered at the Royal Institution, by Professor Maxwell, in which he mooted the novel theory that the three primary colours instead of being, as is commonly, red, blue, and yellow, are red, blue, and green. As our readers know, the latter colour is generally held to be a secondary colour, the product of a mixture of the two primaries yellow and blue, in the same way that purple is the product of a mixture of red and blue, and orange of the mixture of red and yellow. Professor Maxwell holds, however, that green is not a secondary mixed colour, but a simple and primary colour, and that yellow, instead of being a primary colour, is the result of a mixture of red and green; and he illustrated his position by producing yellow by the refraction through a prism of red and green light. The lecture was further illustrated by photographic transparencies taken for the purpose by Mr. Sutton, who in the *Notes* gives the following account of their production:—

"A bow made of ribbon, striped with various colours, was pinned upon a background of black velvet, and copied by photography by means of a portrait lens of full aperture, having various-coloured fluids placed immediately in front of it, and through which the light from the object had to pass before it reached the lens. The experiments were made out-of-doors, in a good light, and the results were as follow:—

"1st. A plate-glass bath, containing the ammoniacal sulphate of copper which chemists use for the blue solution in the bottles in their windows, was first placed immediately in front of the lens. With an exposure of six seconds a perfect negative was obtained. This exposure was about double that required when the coloured solution was removed.

"2nd. A similar bath was used, containing a green solution of chloride of copper. With an exposure of twelve *minutes* not the slightest trace of a negative was obtained, although the image was clearly visible upon the ground-glass. It was, therefore, found advisable to dilute the solution considerably; and by doing this, and making the green tinge of the water *very* much paler, a tolerable negative was eventually obtained in twelve minutes.

"3rd. A sheet of lemon-coloured glass was next placed in front of the lens, and a good negative obtained with an exposure of two minutes.

"4th. A plate-glass bath, similar to the others, and containing a strong red solution of sulpho-cyanide of iron was next used, and a good negative obtained with an exposure of eight minutes.

"It is impossible to describe in words the exact shades of colour, or intensity of these solutions. The thickness of the fluid through which the light had to pass was about three-quarters of an inch. The collodion was simply iodized, the bath neutral, and the developer pyrogallic acid. The chemicals were in a highly-sensitive state, and good working order, producing clean and dense negatives, free from stains and streaks in all cases.

"The negatives taken in the manner described were printed by the tannin process upon glass, and exhibited as transparencies. The picture taken through the red medium was at the lecture illuminated by red light,—that through the blue medium, by blue light,—that through the yellow medium, by yellow light, and that through the green medium, by green light;—and when these different-coloured images were superposed upon the screen, a sort of photograph of the striped ribbon was produced in the natural colours."

Mr. Sutton concludes from these experiments that yellow glass is not so good for the windows of dark rooms, &c., as red or green glass. This idea would scarcely accord with the results the spectroscopic analysis of various-coloured glasses recorded in our "Scientific Gossip." Red glass, of some kinds, is found indeed to be quite impervious to actinic light; but the colour is so irritating to a sensitive eye as to be practically useless. The resistant power of green to the passage of the actinic rays is strikingly shown in the experiment narrated; but it can scarcely be assumed, as following, that green glass would necessarily have a similar effect. Green we know is, at least often, formed of a mixture of blue and yellow, and in such proportion as blue may be present, it may be expected to possess an actinic character. It will be seen, from the spectroscopic examination of a piece of green glass, that it is, in one instance at least, comparatively speaking, worthless for the purposes of the dark room. If we rightly understand the statement of the case, moreover, it was lemon-coloured, and not a deep yellow, or orange-coloured glass which was used in these experiments, and it might be expected *à priori* to permit of the passage, to a large extent of actinic light. The subject is very interesting, and we commend it to the attention of our readers, as also the following abstract of Professor Maxwell's lecture which we extract from the *Notes* to which the Professor had contributed it:—

"The speaker commenced by showing that our power of vision depends entirely on our being able to distinguish the intensity and quality of colours. The forms of visible objects are indicated to us only by differences in colour or brightness between them and surrounding objects. To classify and arrange these colours, to ascertain the physical conditions on which the differences of coloured rays depend, and to trace, as far as we are able, the physiological process by which these different rays excite in us various sensations of colour, we must avail ourselves of the united experience of painters, opticians, and physiologists. The speaker then proceeded to state the results obtained by these three classes of enquirers, to explain their apparent inconsistency by means of 'Young's Theory of Primary Colours,' and to describe the tests to which he had subjected that theory.

"Painters have studied the relations of colours in order to imitate them by means of pigments. As there are only a limited number of coloured substances adapted for painting, while the number of tints in nature is infinite, painters are obliged to produce the tints they require by mixing their pigments in proper proportions. This leads them to regard these tints as actually compounded of other colours, corresponding to the pure pigments in the mixture. It is found that by using three pigments only we can produce all colours lying within certain limits of intensity and purity. For instance, if we take carmine (red), chrome (yellow), and ultramarine (blue), we get by mixing the carmine and the chrome all varieties of orange passing through scarlet to crimson on the one side, and to yellow on the other. By mixing chrome and ultramarine we get all hues of green, and by mixing ultramarine with carmine we get all hues of purple, from violet to mauve and crimson. Now these are all the strong colours that we ever see or can imagine, all others are like these, only less pure in tint.

"Our three colours can be mixed so as to form a neutral grey, and if this grey is mixed with any of the hues produced by mixing two colours only, all the tints of that hue will be exhibited, from the pure colour to the neutral grey. If we could assume that the colour of a mixture of different kinds of paint is a true mixture of the colours of the pigments, and in the same proportion, then an analysis of colour might be made with the same ease as a chemical analysis of a mixture of substances.

"The colour of a mixture of pigments, however, is often very different from a true mixture of the colours of the pure pigments. It is found to depend on the size of the particles, a finely-ground pigment producing more effect than one coarsely ground. It has also been shown by Professor Helmholtz, that when light falls on a mixture of pigments, part of it is acted on by one pigment only, and part of it by another, while a third portion is acted on by both pigments in succession before it is sent back to the eye. The two parts reflected directly from the pure pigments enter the eye together, and form a true mixture of colours, but the third portion, which has suffered absorption from both pigments, is often so considerable as to give its own character to the resulting tint. This is the explanation of the green tint produced by mixing most blue and yellow pigments.

"In studying the mixture of colours we must avoid these sources of error, either by mixing the rays of light themselves, or by combining the impressions of colours within the eye by the rotation of coloured papers on a disc.

"The speaker then stated what the opticians had discovered about colour. White light, according to Newton, consists of a great number of different kinds of coloured light, which can be separated by a prism. Newton divided these into seven classes, but we now recognise many thousand distinct kinds of light in the spectrum, none of which can be shown to be a compound of more elementary rays. If we accept the theory that light is an undulation, then, as there are undulations of every different period from the one end of the spectrum to the other, there are an *infinite* number of possible kinds of light, no one of which can be regarded as compounded of any others.

"Physical optics does not lead us to any theory of three primary colours, but leaves us in possession of an infinite number of pure rays with an infinitely more infinite number of compound beams of light, each containing any proportions of any number of the pure rays.

"These beams of light passing through the transparent parts of the eye fall on a sensitive membrane, and we become aware of various colours. We know that the colour we see depends on the nature of the light, but the opticians say there are an infinite number of kinds of light, while the painters, and all who pay attention to what they see, tell us they can account for all actual colours by supposing them mixtures of three primary colours.

"The speaker next drew attention to the physiological difficulties in accounting for the perception of colour. Some have supposed that the different kinds of light are distinguished by the time of their vibration. There are about 447 billions of vibrations of red light in a second, and 577 billions of vibrations of green light in the same time. It is certainly not by any mental process of which we are conscious that we distinguish between these infinitessimal portions of time, and it is difficult to conceive any mechanism by which the vibrations could be counted, so that we should become conscious of the results, especially when many rays of different periods of vibration act on the same part of the eye at once.

"Besides, all the evidence we have on the nature of nervous action, goes to prove that whatever be the nature of the agent which excites a nerve, the sensation will differ only in being more or less acute. By acting on a nerve in various ways, we may produce the faintest sensation or the most violent pain; but if the intensity of the sensation is the same, its quality must be the same.

"Now we may perceive by our eyes a faint red light which may be made stronger and stronger till our eyes are dazzled. We may then perform the same experiment with a green light or a blue light. We shall thus see that our sensation of colour may differ in other ways, besides in being stronger or fainter. The sensation of colour, therefore, cannot be due to one nerve only.

"The speaker then proceeded to state the theory of Dr. Thomas Young, as the only theory which completely reconciles these difficulties, in accounting for the perception of colour. Young supposes that the eye is provided with three distinct sets of nervous fibres, each set extending over the whole sensitive surface of the eye. Each of these three systems of nerves when excited gives us a different sensation. One of them, which gives us the sensation we call red, is excited most by the red rays, but also by the orange and yellow, and slightly by the violet. Another is acted on by the green rays, but also by the orange and yellow, and part of the blue, while the third is acted on by the blue and violet rays. If we could excite one of these sets of nerves without acting on the others, we should have the pure sensation corresponding to that set of nerves. This would be truly a primary colour, whether the nerve were excited by pure or by compound light, or even by the action of pressure or disease.

"If such experiments could be made, we should be able to see the primary colours separately, and to describe their appearance by reference to the scale of colours in the spectrum. But we have no distinct consciousness of the contrivances of our own bodies, and we never feel any sensation which is not infinitely complex, so that we can never know directly how many sensations are combined when we see a colour. Still less can we isolate one or more sensations by artificial means, so that in general, when a ray enters the eye, though it should be one of the pure rays of the spectrum, it may excite more than one of the three sets of nerves and thus produce a compound sensation. The terms simple and compound, therefore, as applied to colour sensation, have by no means the same meaning as they have when applied to a ray of light.

"The speaker then stated some of the consequences of Young's theory, and described the tests to which he had subjected it.

"1st. There are three primary colours.

"2nd. Every colour is either a primary colour or a mixture of primary colours.

"3rd. Four colours may always be arranged in one of two ways. Either one of them is a mixture of the other three, or a mixture of two of them can be found identical with a mixture of the other two.

"4. These results may be stated in the form of colour equations giving the numerical value of the amount of each colour entering into any mixture. By means of the colour top such equations can be obtained for coloured papers, and they may be obtained with a degree of accuracy showing that the colour-judgment of the eye may be rendered very perfect.

"The speaker had tested in this way more than one hundred different pigments and mixtures, and had found the results agree with the theory of three primaries in every case. He had also examined all the colours of the spectrum with the same result. The experiments with pigments do not indicate what colours are to be considered as primary, but experiments on the prismatic spectrum show that all the colours of the spectrum, and therefore all the colours in nature, are equivalent to mixtures of three colours of the spectrum itself, namely, red, green, and blue. Yellow was found to be a mixture of red and green.

"The speaker, assuming red, green, and blue as primary colours, then exhibited them on a screen, by means of three magic lanterns, before which were placed glass troughs containing respectively sulpho-cyanide of iron, chloride of copper, and ammoniated copper. A triangle was thus illuminated, so that the pure colours appeared at its angles, while the rest of the triangle contained the various mixtures of the colours, as in Young's triangle of colours. The graduated intensity of the primary colours in different parts of the spectrum was exhibited by three coloured images, which, when superposed on the screen, gave an artificial representation of the spectrum.

"Three photographs of a coloured riband, taken through the three coloured solutions respectively, were introduced into the camera, giving images representing the red, the green, and the blue parts separately, as they would be seen by each of Young's three sets of nerves separately. When these were superposed, a coloured image of the riband was seen, which, if the red and green images had been as fully photographed as the blue, would have been a truly-coloured image of the riband. By finding photographic materials more sensitive to the less refrangible rays, the representation of the colours of objects might be greatly improved.

"The speaker then proceeded to exhibit mixtures of the colours of the pure spectrum. Light from the electric lamp was passed first through a narrow slit, a lens, and a prism, so as to throw a pure spectrum on a screen containing three moveable slits, through which three distinct portions of the spectrum were suffered to pass. These portions were concentrated by a lens on a screen, at a distance forming a large uniformly-coloured image of the prism. When the whole spectrum was allowed to pass, this image was white, as in Newton's experiment of combining the rays of the spectrum. When portions of the spectrum were allowed to pass through the moveable slits, the image was uniformly illuminated with a mixture of the corresponding colours. In order to see these colours separately, another lens was placed between the moveable slits and the screen. A magnified image of the slits was thus thrown on the screen, each slit showing, by its colour and its breadth, the quality and quantity of the colour which it suffered to pass. Several colours were thus exhibited, first separately and then in combination. Red and blue, for instance, produced purple; red and green produced yellow; blue and yellow produced a pale pink; red, blue, and green produced white; and red and a bluish-green produced a colour which appears very different to different eyes.

"The speaker concluded by stating the peculiarities of colour-blind vision, and by showing that the investigation into the theory of colour is truly a physiological enquiry, and that it requires the observations and testimony of persons of every kind, in order to discover and explain the various peculiarities of vision."

THE PARADOX OF THE SOLAR SPECTRUM.

BY S. D. TILLMAN, A.M.*

An apparent anomaly in the solar spectrum has heretofore been the subject of discussion before this Society. A further elucidation of it is the object of the present paper. The generally accepted undulatory theory of light is commended for its simplicity in referring all luminous calorific and actinic effects to the action of a single all-pervading imponderable fluid.

The undulations of ether or eeth-waves in their length and velocity have a direct relation to the heating and chemical power of the sunbeam. Heat is found in maximum beyond the red ray of the solar spectrum, and in minimum beyond the violet ray, decreasing regularly from the red to the violet while actinism acts inversely. The heating power being directly as the length of the wave, and the actinic power directly as the velocity of the wave. The luminous power, on the contrary, seems to obey the heat-law from the red to the yellow, the actinic law from the yellow to the blue, and again the heat-law from the blue to the violet, in other words, both the most and least luminous rays are found within the extremities of the solar spectrum. Thus, while light is said to depend upon undulations, paradoxical as it may appear, the degree of luminosity has no relation in reality to a regular increase in the length or the velocity of such undulations. Another phenomenon, involving an apparent paradox, is found in the union of the primary series of waves; if to the yellow ray, the most luminous of the spectrum, is added the red, a darker ray, and the blue, a still darker ray, the resultant is white light.

In the sunbeam, when decomposed by the prism, the arrangement of colours and the degrees of luminosity bear a marked analogy to order of concords of sound. The eye and ear, although differing widely in their capacity to receive the impression of wave forces, exercise similar offices in conveying to the mind the mysterious influence arising from harmony. Fortunately this similarity in the effects of light and sound will enable us to illustrate the action of the former by the latter in statements of proportions where high numbers and intricate diagrams would tend to confuse rather than enlighten.

The brilliancy of the yellow ray of the spectrum and of the mediant chord in the septave arises from the fact that the waves producing them have remarkable harmonic relations with the remainder of the series. If the number of waves producing the tonic or fundamental sound be taken at 24, that for the mediant will be 30, and that for the dominant will be 36. The sum of the tonic and dominant waves (corresponding with the red and blue rays) is just double the number of waves producing the mediant which corresponds with the yellow ray. The sum of all the waves causing the septave series of sounds, excluding the tonic, is found to be 210 or just seven times 30, the number belonging to the mediant.

The sound corresponding with the darkest ray is the submediant, it has no such relations with other sounds as belong to the brilliant mediant, except in the case where the subdominant becomes the tonic, and it then is the mediant of the new modulation, showing clearly that it is *the relations*

* Read before the American Photographical Society, June 10, 1861.

of pitch and not the pitch itself which produce these peculiar effects.

If the tonic is taken as 1, its octave will be 2, and the ratios expressing the other sounds of the septave will have one term which is a multiple of the prime number 2 with the exception of the peculiarly depressing sound known as the relative minor tonic whose ratio with the major tonic is expressed by the higher prime numbers 3 and 5. Thus while the tonic and its octave which produce the most perfect harmony are represented by the increase of the unit by geometrical progression, all other chords will produce effects proportional to their ratios. So, likewise, luminosity in degree depends not on actual but relative velocities of vibration.

The musician may vary the expression of his composition by the *timbre* of his instrument and by the intensity of sound, yet the latent and lasting power of the melody lies in the arrangement of sounds, that is, in the sequence of ratios. So also the painter produces most striking and permanent effects, not by the presence or absence of luminosity as measured from a fixed standard by the *harmonic relations* of colours which like those of sound may be expressed in numerical ratios, thus resolving all effects through the eye into resultants of a sequence of velocities each of which may be represented by a definite mathematical expression.

BOTTLES EXPLODING.

A singular circumstance is related in a recent number of the *American Journal of Photography* under the head of "Explosion of a collodion bottle," in which the writer is at considerable pains to show that the explosion was due to the bottle itself, and did not arise from any expansion or vapourising of the collodion. The bottle was of glass, and contained two gallons of collodion, which had stood for a week when the explosion took place.

"While everything in the room was perfectly quiet we heard such a sound as about a cubic foot of water let drop all at once (not poured) from a small height would make, accompanied at the same time with the smashing of about a gross of wine glasses. My first impression was that a tank of croton,* in the room above us, had come in a deluge on my chemical apparatus. But an immediate odour of ether, and a river of collodion flowing across the floor, shewed at once that my bottle of fine collodion was smashed, and that we were in danger of our lives. I ordered all the windows to be opened at once, leaped to the story below to put out any fire which might be burning there; but luckily it was a warm day and no fire was burning in the building. We were safe.

"We scooped and wiped up the thickening collodion on the floor, and then began to speculate on the cause of the phenomena. We established in the first place that the expansion of the collodion vapours did not explode the bottle; I am always careful to guard against accident from that cause, and the cork, which we found, was conclusive against such a theory. Nothing could have fallen on to the bottle, or have been thrown against it. The cause of the accident must be sought not in the contents of the bottle, not in the bottle nor in anything outside of it, but in its very substance. This reasoning and conclusion were but reached in a hurry. My friend Thornbrook, and I, before we were prepared to adopt it, gave the whole case careful scrutiny, and discoursed profoundly of our former experience and the teachings of books. While we were thus talking, half-a-dozen assisting, another thing happened which was quite as unexpected and mysterious as the original disintegration of the bottle.

"The bottom of the bottle entire, still lay on the table and had not been touched. It apparently had not been touched in a week. We were all standing around the table as above described, when we heard a sharp crack, precisely like an explosion of a percussion cap, and at the same time, a thin slice from the upper rim of the bottle keeled away over on to the table. This fragment was in average about one-third inch thick, and was about two-thirds of a complete ring. The surface of fracture was exceedingly uniform grooved, curved and polished, as if it had been the handiwork of an artist; indeed, it was suggested that the bottle had been joined together in a series of ground rings.

"The simple statement of the case seems to be, that a glass bottle, quietly standing, went to pieces, and that this is a very strange accident. If it had been an unannealed bottle, or if it had just come out of a store, I would not think so much of it. But it was a favourite bottle, which I had used for years, and I had got it at first from a photographer who had used it for a long time before."

In a subsequent number of the same journal Mr. Coleman Sellers, one of its most intelligent contributors, gives an interesting explanation of this curious fact, from which our readers may learn something. He remarks:—

"The marvellous stories of the feats of eastern jugglers, as told by eye witnesses, impress us with wonder, and we can find no solution of these mysteries, simply because we have not heard the whole story; the attention of the narrator was drawn away from the important movements by some by play, and what he did not see, is not, of course, related to us. So with the troubles of photographers, they detail all they have done in some cases, and the routine of their operations seeming right, they wonder at their failure. Some little act of careless omission or commission, is neglected and we can do nothing to help them in their trouble.

"Not so, however, with the explosion of the collodion bottle so pleasantly told in the last number of this journal, (and most sincerely do I sympathise with the author); he tells all the story in saying, "I spent about twenty minutes on the bottle, assisted with a *bottle-brush*, water, and alcohol." Here was the rub; that bottle-brush was most likely the criminal. It was perhaps made of wire twisted, having projecting bristles; the wire was doubtless iron, and may be a very little rusty. Glass is a very ticklish substance, and don't like to be scratched inside. If any of my readers would try the experiment, they can convince themselves of this fact by the following. Through a clean glass tube, new or old it matters not which, let them then draw an iron wire just a little rusty; then let them lay the tube away in a drawer, under lock and key. It now will be only a matter of time when that tube shall go into a thousand pieces spontaneously,—but go it will most assuredly, if not in a few days, in a few weeks, but often in a few hours.

"It is a well-known fact that if the inside of a glass tube be touched by a rough iron wire it will be scratched, and that scratch, though ever so slight, will be the starting point from which the disintegration of the tube will radiate; and the fraction is always in rings, and of a conchoidal form. The writer was many years ago speaking of this to Dr. John Locke, of Cincinnati. The Doctor related many amusing anecdotes illustrative of the fact, and said that it was his rule in cleaning glass tubes, to drop through the tube a lead plummet attached to a sink cord through an eye in this plummet, he would then assist the cotton cloth to be drawn back through the tube, thus cleaning it.

"The same in relation to bottles, he would use no iron wire in cleaning either. Glass, no matter how well annealed, is always under some strain, and is more liable to break from an internal than from an external scratch.

"An experiment illustrating this is often shown in glass works, a tumbler cooled in the air, is placed bottom up on a board, over it some sand could be thrown with impunity, but when a few grains of the same sand are dropped inside of the glass it will at once fly into countless pieces. Let, therefore, the explosion of that collodion bottle in New York, be a warning to all who take to the bottle in a legitimate way, never to tickle its inside with an iron wire, for it surely will laugh itself to pieces and to the consternation of the innocent operator."

Dictionary of Photography.*

Pyroxyline.—*continued.*—The parchmentized soluble cotton, obtained by the use of a large excess of sulphuric acid, does not possess the physical properties usually considered desirable in a collodion intended for the dry processes. Amongst the essentially necessary conditions for a dry collodion, a pyroxyline yielding a powdery porous film has generally been considered important, on the ground that it is more easily permeable by aqueous developing solutions, and less

* Water from the Croton aqueduct.

* Continued from p. 352.

apt to blister or leave the glass. To secure a pyroxyline yielding such a film, various methods have been proposed. Mr. Hardwich has suggested immersing for a few seconds the parchmentized pyroxyline already described, in nitro-sulphuric acid, mixed in the inverse proportions to that with which it was made, or three parts of nitric acid, sp. gr. 1·450 and one part of sulphuric acid, at a temperature of 150°. The operation of these acids upon the tough pyroxyline is to render it rotten and powdery in texture, and to make it give a porous permeable film with considerable tendency to density of image. The action of alkalies on pyroxyline has also a tendency to cause a rotten film. To produce this effect it is added to the plain collodion.

The formula we have given, as propounded by Mr. Hardwich, although unquestionably producing a collodion possessing many desirable characteristics, has a tendency, if the greatest precision be not observed in all the conditions, to cause entire dissolution of the cotton in the acids, and is scarcely suitable for the use of amateurs or others not intending to enter commercially into the manufacture of pyroxyline. We shall now proceed, therefore, to describe a method which has been universally successful in our own hands, and the appliances for which are simple and easily acquired.

Procure, in the first place, an earthenware jar, holding about a pint, and a deep earthenware dish, within which the jar can stand. Also procure a couple of stout glass rods about twelve inches long, a couple of glass spatulas the same length, and about an inch broad, will answer still better. Have also ready a kettle of boiling water and a pail of cold water. Now take of nitric acid sp. gr. 1·420 three measured ounces, and of sulphuric acid sp. gr. 1·840 three measured ounces, and put them into the pint jar which is standing in the larger dish. In this larger dish pour the boiling water so that it may surround the sides of the jar containing the acids. The temperature of the acids will rise when they are mixed, but probably not sufficiently, and it must be raised by means of the hot water in the outer vessel until it reaches 150° Fah. The cotton, which should be the best sample procurable, well carded and free from all impurities, should have been prepared previously; a quarter-of-an-ounce is the proper proportion for the quantity of acids named. It should be separated into tufts, well pulled out, into about the size of a penny piece. These should be immersed in the acids, at the temperature stated, one at a time, and pushed quickly down into the acids, with the glass rod, and pressed against the side of the jar. The whole should be as rapidly immersed as possible, care being taken to prevent it rising above the surface of the acids, and so coming into contact with the atmosphere, which would endanger the formation of red nitrous fumes and the entire dissolution of the cotton. When all the cotton is immersed, a plate of glass may be placed on the top of the jar to prevent the acids from cooling, and the whole left for ten minutes.

Now seize the whole of the cotton between the glass rods, and pressing out as much of the acids as possible, quickly pass it into the pail of water which has been provided beforehand for the purpose, and quickly stir the cotton about so as to distribute it rapidly through the water. If care be not taken in this respect, the acids left in the cotton being diluted with the water, it occasionally happens that the whole of the cotton is dissolved at this stage. It should, therefore, be as rapidly as possible pulled from together, and distributed through the whole pail of water to stop as quickly as possible the effect of the acids. In a few minutes the water should be changed, and so for a quarter-of-an-hour, giving not less than half-a-dozen changes of water during that time. It should then be placed under a stream of turning water for a few hours, after which, if a piece of blue litmus paper remain unchanged in the water, the cotton is sufficiently washed. In some cases, where time is an object, a few drops of strong ammonia may be added to one of the final washing waters, after which wash well with rain water. Some authorities have objected to the use of ammonia for neutralising any traces of acid remaining after long washing, but after considerable experience in its use, we have never found any disadvantage arising from it.

After the cotton is thoroughly washed it should have the water wrung from it, and be pulled out so as to be as open as possible, and spread upon a large sheet of paper to dry. This may be done spontaneously in a warm place, or it may be more quickly effected by the aid of a water bath. It should on no account be placed in an oven, on the hob, or, indeed, in any place near a fire, as we have in many cases known explosions, which might have been attended with serious consequences, result from such modes of drying. Where a small quantity for immediate use is required to be dried quickly, it may, after pressing as much water as possible, be immersed in alcohol which will absorb the remaining water, and it will then on pulling out, rapidly dry. When the washing is completed the best mode of getting rid of as much water as possible, is to place the cotton in a clean napkin, and then wring it thoroughly until not another drop of water can be pressed out of it.

The pyroxyline produced by the formula we have just described ought to be somewhat short, but not rotten in texture. Not entirely explosive, but burning rapidly, just on the point of explosion, and leaving no ash. It should dissolve entirely in a mixture of equal parts of ether and alcohol, and give an even somewhat tough film, and thus present physical properties suitable for either positives or negatives.

For the convenience of those who may have difficulty in obtaining nitric acid of the strength we have named, we may state that the specific gravity of the nitric acid usually sold as "pure nitric acid," without any statement of its strength, generally contains more water than that we have named, and very commonly possesses a specific gravity of 1·360. With nitric acid of this strength, and the oil of vitriol of commerce as the sulphuric acid, the proportions should be in the ratio of six measured ounces of the latter to four measured ounces of the nitric acid. This at a temperature of 150° will give a very excellent cotton, perhaps a little shorter, and more suited to negative purposes than the former, but dissolving perfectly, and giving an even structureless film adhering well to the glass. In both cases the increase in weight will be from thirty to fifty per cent.

Where a pyroxyline solely for positive purposes is required, the temperature might with advantage be reduced to 140° or 135°. The result of which would be a little less intensity in the character of the image given, a little more transparency in the shadows, and more silvery whiteness in the image by reflected light.

Where pyroxyline is made with acid containing a little more water, or at a higher temperature, or with both conditions, the cotton becomes shorter and more powdery in texture, gives a thinner and more textureless film, which is somewhat porous in character, and at a certain stage acquires the quality of forming, to a certain extent, an organic compound with silver, which causes it to give a very intense image. It is to be understood that weaker acids, at the same temperature, or the same acids at a higher temperature, would in either case produce similar results. That is weak acids at a moderate temperature, or stronger acids at a very high temperature each tend to the production of a cotton giving, in collodion, a powdery film and somewhat intense image. The best mode of securing this end, therefore, is by a judicious combination of the two means thus presented. Thus with acids of the same strength, the temperature may be gradually increased up to 160° or even 180°, and at the same time additions of water, made at the rate of from half-a-drachm to a drachm at a time, for each fresh batch of cotton made, until a cotton of the desired quality, suitable for dry, or other purposes requiring the organic character, be obtained. The point to be guarded against when the maximum of water has been added, and the maximum of heat obtained, is the entire solution of the cotton in the acids, and the evolition of red nitrous fumes.

Other substances besides cotton wool have been used for the manufacture of pyroxyline, such as linen, flax, paper, &c., but cotton wool has been found to answer general purposes much the best. Paper has, indeed, been frequently commended as giving a more fluid, structureless, and intense collodion than the pyroxyline made from cotton wool. Against this it has been very justly urged that paper is a mixed and uncertain compound, and can never be guaranteed to be twice exactly the same article. Notwithstanding this argument, many photographers prefer its use; and we are bound to add that in our hands many traits of its excellent character have been fully exemplified, and a pyroxyline, possessing all the most desirable characteristics for a negative collodion, has been the result of its use. Good white blotting paper, or that known as Swedish filtering paper, is the most suitable for the purpose. It should be cut into strips about half-an-inch wide, and crimped a little to cause it to lie loosely in the acids, and allow them to surround it properly. The formula and manipulations are, in other respects, the same as for cotton.

It is desirable for the amateur and novice not to work with too large a quantity of material at one time. The quantity we have mentioned, a quarter of an ounce of cotton, making nearly three drachms of pyroxyline, is quite sufficient for convenient manipulation, and when larger quantities are tried, the risk of failure from various causes is much increased.

It is desirable for the manipulator to wear, during these operations, india-rubber gauntlets, to protect the hands and wrists both from the fumes and splashes of the acids. The fumes alone are apt to colour the fingers and nails of a disagreeable yellow tint, which cannot be readily removed, whilst any splashes falling on the skin are very corrosive, and quickly produce serious wounds. Great care should be used to avoid splashes at all, as of course the clothes or any other fabric on which the acids may fall will inevitably be destroyed in such places.

It is always desirable that the operation be conducted under a chimney, where there is a good draught of air, so as to convey away any fumes which may arise; or, it may be conducted in the open air, the manipulator standing to windward. The ordinary vapours of the nitrosulphuric acid are neither pleasant nor wholesome, and should be carefully avoided. Should the red nitrous fumes be evolved during the operation, the first effort should be to stop the progress, by punching down the part, from which they arise, into the acids. Should it be found impossible to arrest the progress, it will be better to leave the apartment at once, leaving open the door and window, risking the loss of the pyroxyline rather than the loss of life, which might be the consequence of breathing these deadly fumes.

Pyroxyline should be kept in a dry place and in the dark, a tin box with a loose fitting cover answering the purpose for keeping it admirably.

(*To be continued.*)

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 7th August, 1861.

Another revolution in photography! The honour of achieving this result is due to Sig. Joseph Eugéne Balsamo, Professor of Natural Philosophy at Lecca, in Italy, who has found a substitute for nitrate of silver in positive printing, which is hydrochloric acid saturated with phosphorus, and diluted with acetate of copper. Paper imbued with this compound is exposed to the action of light under a negative, and when it has acquired a gray colour, it is removed from the pressure-frame and exposed for five minutes to the vapours of sulphuretted hydrogen, which acts upon those parts of the paper which have become altered by the action of light. The picture is afterwards toned and fixed in a solution of nitrate of bismuth. A decomposition of the salt of copper takes place, and the image, which is permanent is formed of oxide of bismuth. The professor, with that true liberality which characterizes men of science, has given his discovery to the world, His researches in heliography have opened a new path to the photographer, and he promises another communication on this subject ere long.

I can almost chronicle even another revolution in photography, in which collodion sensitized with nitrate of silver will be dethroned; but what the new photogen consists of I am at present unable to say. But its discoverer, M. Gaudin, is one not prone to rash assertions, therefore we may look hopefully to the result of his experiments to the attainment of the result indicated. Of this result he speaks most confidently, and it is to be hoped that he will not withhold the information so long as to render his reticence tantalizing.

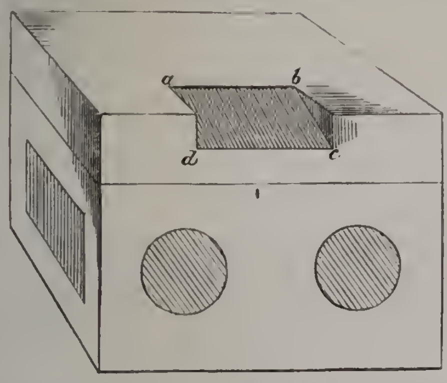
M. Gaudin, commenting on Mr. Barber's paper on "a new method of preparing pure nitrate of silver by means of alloys of silver and copper," remarks, that a nitrate of silver rendered blue by the presence of copper would be unsaleable, while a nitrate of silver adulterated and whitened with the salts of potash finds ready acceptance, and yet, nothing is less certain than the presence of copper in the nitrate being injurious, while from what has often occurred to M. Gaudin, he strongly suspects that the presence of copper is quite advantageous than otherwise. For whenever he prepared nitrate of silver from silver coin, without completely separating the copper, he always found the nitrate of silver to possess a remarkable sensibility, which he estimates to be not less than four times the sensibility of pure nitrate of silver. But whether he made the comparison between a good cupreous nitrate of silver, and an adulterated commercial nitrate, he is unable to state, so that the question of the superiority of cupreous nitrate must remain open, until it has been strictly tested. At present, however, M. Gaudin does not hesitate to say that every photographer who gives himself the trouble to remove all traces of copper from his nitrate of silver, is guilty of a piece of gratuitous folly; for it is certain, that the presence of nitrate of copper cannot be more injurious than all the other nitrates formed in the bath while in use, while it may prove to be a great accelerator; for the iodide of copper is insoluble, and when a plate is sensitized iodide of silver and iodide of copper are both formed on the collodion film; and as in photography rapidity is always due to the addition of foreign bodies in minute quantities, copper, thus far, appears to present all the characteristics of an accelerating agent.

Still another revolution in photography! Mr. Wothly, of Aix-la-Chapelle, writes under date of 27th ultimo, that after many years of research, he has succeeded in obtaining positive portraits without nitrate of silver, or chloride of gold, or carbon, or hyposulphite of soda, in a word, without any of the photographic agents usually employed. They are replaced by a simple chemical preparation, much more sensitive than nitrate of silver, which renders all retouching unnecessary when the negative is free from defects. All his positives from *carte de visite* to the life-size, have a striking appearance; the modelling is of exquisite delicacy and the tones are as brilliant as can be desired. The manipulation remains the same; every photographer can perform it without any difficulty, with this great advantage, that he can deliver his portraits within two or three hours after the sitting. The new photographs are indestructible; they will endure as long as the paper upon which they are printed, and are 95 per cent. cheaper than those produced by the present method. This is marvellous; but we withhold our credence for ocular demonstration.

Apparatus.

DEVELOPING BOX.

Sir,—Seeing in a recent number of the News a notice of a dark box by "C. S." I forward you one that I have in use. Its dimensions are 2¼ ft. by 1½ ft. by 1½ ft. deep. There is a square piece out of the back 7½ by 6½ inches, the bottom of which is 3¼ inches from the bottom edge of the box. I have it thus low in order that the plate when developing may be right between it and the glass *a*, *b*, *c*, *d*. I find it



far better to have the piece *a*, *b*, *c*, *d*, as represented in the diagram, than inserted in the horizontal plane of the lid. The lid is 3 inches deep; the glass *a*, *b*, *c*, *d*, is 7 by 4 inches. The side holes are 6 inches square, common glass, on the inside of which I have pasted three thicknesses of red tissue paper; all three vertical windows have curtains inside, the window at the back having yellow paper instead of red. The wood cut out of the lid fits in with a button for travelling. The front holes are 7 inches diameter and 7 inches apart. The whole is painted *white* to throw off the rays, and thus to keep the inside cool. I use for developing a black cloth tied round my neck and lined with white, so that when in action the white is outermost and keeps the head cool of Your obedient servant,

J. C. B.

P. S.—Round the front holes I have nailed black cloth, with two pieces of elastic on *each* to fit the arm. The box holds all chemicals and two cameras. The whole goes on to a small wheelbarrow.

A SIMPLE DARK TENT.

Sir,—As you say in you 143rd number that you will be glad to receive hints from any of your readers upon the subject of "tents," and as I am indebted to your useful paper for many valuable hints, I here give you, as a trifling acknowledgment, a description of a tent which was suggested to me by Dame Necessity some three or four years ago, whilst I was residing in the most distant settlement of of the British Colonies in the Pacific Ocean, Nanaimo, Vancouver's Island, where I had none of the advantages possessed by the readers of the Photographic News for the benefits to be derived from a knowledge of the experience of others, can only be fairly appreciated when the want of that knowledge is felt. As I left England soon after Mr. Archer's discovery of the collodion process was made known, I did not know of the existence of the Photographic News until some two or three months after my return home, in the last year (1860).

The construction of my tent is so simple that it may be made by the poorest mechanic, and its cheapness brings it within the reach of the poorest photographer, as it need not, I think, cost more than 5s. or 6s. besides his own trouble in making it.

I first took three rods of deal, each about 8 feet in length and 1½ inches square; within an inch of the one end of each I made a small hole, I then passed through each of these holes a piece of strong wire, the two ends of which I twisted together, thereby making it into a ring, but of sufficient size as to allow a free action of the deal rods, which now hung upon it in the same manner as the ribs of an umbrella hang upon the wire ring at the end of the handle. I then erected it upon its feet in the shape of a tripod-stand, and as I could not there obtain either "yellow calico," or "yellow tammy" I covered it with *white* calico, which I afterwards painted "yellow," leaving an entrance upon the one side, over which I placed a loose curtain of the same material. My tent I usually carried upon my shoulder, and my apparatus, &c., in a light box, which latter, when emptied of its contents, I used to put inside my tent, and thus made it serve as a rather low operating table. In this tent almost any sized plate may be manipulated upon.

I have enclosed a print from a negative developed in said tent.—I am, sir,

A Pupil of a Californian Photographer.

June 15, 1861.

WOODEN SILVER-BATHS.

We have recently tried one of the wooden silver-baths, intended especially for use in tents and developing boxes, made by Mr. Francis, of Great Russell Street. The bath is made of deal, and furnished with a water-tight top; instead of being coated inside with a varnish of shellac, it is lined throughout with thin sheet india-rubber, which passes through between all the joints. Instead of being glued together it is screwed, the india-rubber serving as an elastic washer, and causing it to fit perfectly, without a chance of leakage. It answers the purpose perfectly, being at once light, rigid, and free from the risk of breakage. Pure india-rubber is without action on the solution of nitrate of silver, and may be used safely. It may be as well to add that india-rubber, for such a purpose, should be kept in the dark, as it corrodes under the combined influence of light and moisture, although quite unacted on by moisture alone.

Photographic Notes and Queries.

Stereo-Exchange Club.

Sir,—I am acquainted with several members of the Stereo-Exchange Club, and without exception they express more or less dissatisfaction with its working, complaining that they often receive a worse samplo of pictures than they send, want of interest in tho subjects, &c. They themselves do not appear to be altogethor clear of blame, as they admit that after boing "done" once or twice, they are, to say the loast, not so careful as to what they send out in return themselves.

As I think the club might be of very great interest and advantage to stereo-photographers, I beg to offer a few suggestions which would, I think, if carried out, give a guaranteo for the quality, and allow of mombers selecting their subjects.

I proposo:—That some practical photographer, in whoso judgment the members would have confidenco, bo appointed secretary, to whom all prints intended for exchange should be forwarded, each accompanied with a penny stamp to defray tho expenses of working, the balance to remain with the secretary as some compensation for his trouble.

That the secretary should arrange the prints received into three classes, according to quality, say "good," "medium," "indifferent," forwarding to the member who has contributed them a ticket, in return for which he can claim from the club an equal number of the samo qualities.

That when a sufficient number are on hand, a list of the subjects arranged under their different qualities should be sent to each member to select from, the prints being returned to him by post at tho expense of the society in exchango for his tickets.

Of course minor details would requiro arranging, I merely offer these hints to give an idea of a system of management which I think would be satisfactory in its results.—Yours, &c.,

Stereo.

Wigton, August 3, 1861.

Talk in the Studio.

Photolithographic Processes.—We omitted, in a recent notice of Mr. Ramage's photolithographs, to mention the fact, which may interest some of our readers who are engaged on similar experiments, that he had forwarded to us a specimen of grained ground, of a very fine dotted or stippled character, printed on a thin sheet of gelatine paper, and intended for transfer on to the photolithographic stone. We also received at the same time a piece of a zinc plate, on which a photographic reproduction of an engraving was "bitten-in" by means of acids. We hope shortly to be able to give some details of Mr. Ramage's experiments in this interesting direction.

Mr. James Sant, whose exquisite paintings of children every lover of art is familiar with, was recently elected an Associate of the Royal Academy.

The Exhibition of 1862.—Her Majesty's Commissioners have arranged the principles and general details of the Catalogues for the Exhibition of 1862. Three catalogues will be issued: an "Industrial Catalogue," an "Illustrated Catalogue," and a "Fine-Art Catalogue." All matters of a general kind intended for insertion must be sent in to the secretary before February 1; all advertisements before March 1. The price of the Industrial and Fine-Art Catalogues will be one shilling each. The Illustrated Catalogue, which will mainly concern the Exhibitors, though it will also have a present and permanent interest for the public of spectators, will be produced on a handsome scale, in super-royal 8vo., so as to range with the magnificent work of 1851. The name and address of each Exhibitor will be given, with a brief description of his contribution; the printing and paper of this part of the Catalogue being provided by the Commissioners. Detailed descriptions of articles and woodcut illustrations of them must be paid for by the Exhibitor. Editions of ten thousand copies will be struck off from time to time as they may be demanded by the public. All advertisements must first be submitted to Her Majesty's Commissioners.—*Athenæum.*

Improvement in Cameras.—The specification of an invention, by Mr. Hugh Mac Farlane of Glasgow, which received provisional protection only, describes the intended improvement in cameras as follows:—"This invention relates to improvements in cameras such as are used by photographers, such improvements whilst of a simple and inexpensive character permitting of a slight inclination being given to the picture plate, which is in many cases of great benefit, as is well understood by photographers. In a camera embodying the improvements the back portion of the box, instead of being as ordinarily rigidly fixed to the inner shell which is drawn out with the back, has such inner shell entered loosely a short distance and attached by a single screw or pin at the top, and another at the bottom, so that the back can be inclined slightly in either direction about a vertical axis. The back of the box can be fixed at any inclination by means of a screw working in connection with the guide in the back-supporting flap. A slight inclination about a horizontal axis is obtained by means of a pair of levers inside the box, against which levers the frame for holding the picture plate bears, these levers being inclined by means of pins projecting through slots to the outside, and being fixed by means of external screw nuts."

To Correspondents.

J. G. L.—The mode in which you can best apply blinds to your glass-room will depend entirely upon its construction, and can only be determined by personal inspection. It is desirable to possess a double set of blinds to every part of the room which is glazed. These should be divided into convenient sizes to allow of the light being cut off from any given part, whilst the rest is uncovered. The double set of blinds should consist of one set of white calico, and another of blue, either of which may be used alone, or both together. It would have been better to have had the glass at the north end; as your sitter must be under that end which is not glazed, and by your present arrangement he will be illuminated with a south light. The north light is much the best, as being so much more uniformly steady throughout the whole of the day, as well as being softer.

S. W.—The stereoscopic lens to which you refer is the very best we know for stereoscopic work, portrait and landscape. It is not intended to cover a quarter-plate, but will do so as well as most of the lenses sold as quarter-plate lenses.

Thomas Falconer.—It is purely a matter for experiment, but we have not had opportunity of trying it.

Alpha.—There are two or three modes of taking a building without producing what has been called somewhat paradoxically "converging perpendiculars." You may retire a sufficient distance from it to embrace the whole without tilting the camera. Where its position does not admit of retiring far from it, a short focussed lens including a wide angle may be used. Something may be done by raising the rising front of the camera. And lastly, if you are compelled to tilt the camera, you may use a swing-back and so keep the sensitive plate parallel to the building. You will see that in some cases you are compelled to choose amongst several evils, and it requires judgment in each particular case to choose the least. But with all lenses, if the plane of delineation be not parallel to the object delineated, there will be convergence of lines.

Homo.—Some time ago we went through a series of experiments on the effect of chlorides in collodion. In many cases there was no appreciable difference: in no case any increase in sensitiveness, but, on the whole, a little increase in clearness, and a little improvement in the colour of positives. The results were at best, however, only such as might be obtained with care without the chloride, and as, from the difficulty of getting it into solution, its use was somewhat troublesome; we came to the conclusion that the advantage was scarcely worth the trouble. If your ether had become "ozonized" or acid by keeping, the collodion would become yellow on iodizing. We have known such a thing occur even when a cadmium iodizer was used. The liberation of a little colour is by no means necessarily an evil, especially in the positive process. It is quite possible that the collodion will still work well. Pure iodide of sodium is quite soluble. We have some at present which leaves no residue even in absolute alcohol. Insolubility is a sign of the presence of some impurity. We have never met with the curdy appearance to which you refer, and cannot account for it.

L. S. B.—The pinholes appear to arise from turbidity of some of your preparations. Filter the bath and developer, and take care that your collodion is well settled. Also avoid dust, and clean your plates well. The pictures are over-developed. Tincture of iodine, is iodine dissolved in alcohol. A positive well protected from the atmosphere will be tolerably permanent, no matter what developing formula be used. You may varnish the inside of your can with shellac varnish; but if, as you state, there is only an aperture large enough for a cork, it will be somewhat difficult to get at. The only plan will be to dry it well, and then pour in some of the varnish and cause it to flow over every part, after which pour out the excess and let it dry.

A. B. C.—So far as we can judge from the prints forwarded, the negatives ought to yield better pictures. Use a highly albumenized Rive paper silver bath of a strength not less than 80 grains to the ounce; print in diffused light, not direct sunlight, and tone by that formula given in the Photographic News Almanac, in which acetate of soda is used, instead of carbonate or phosphate; or by the formula given by Mr Eliot in a recent number. Any good bromo-iodized collodion will do; but one giving a fair amount of intensity with iron development is best.

J. C. Barnard.—We will make enquiries and endeavour to ascertain how you may best gain your end. It is a case requiring some consideration.

J. R. Price.—We will write to you shortly.

F. G. L.—To make a copy the full size of the original, you must draw out the body of the camera to double the focal length of the lens. If your camera body is not made to extend so far, you can improvise an extension for the occasion by pulling the body right out and covering over the space between the front and back part with black cloth or black velvet. A copying camera is the right thing for the purpose.

J. Thorp.—The print from a dry plate by Mr. Sisson's gum process is very good indeed, and speaks satisfactorily both for your careful manipulation and the capabilities of the process. Regarding the spots and feebleness in the kept plates, we can only suggest that the washing had not been quite sufficient to get rid of all the free nitrate of silver. Regarding the formula, Mr. Sisson gave it to us exactly as he practises it himself, and we gave it just in the words we received it. The best proportions must be decided by experiment.

M. A.—We cannot speak certainly of the excellence of any negative varnish which is applied without heat. See notice of some new varnishes on another page. The fact of your collodion working well when poured from the stock-bottle, and entirely failing when used from the pouring bottle is utterly inexplicable to us. There is nothing, that we know of, in the sea air which ought to produce such results. We have only found a very great accession of sensitiveness in the vicinity of the sea. We have before us at this moment an instantaneous negative, with fine clouds, recently taken with a triple lens at the sea side.

H. Jennings, Jun., wishes to prepare some sulphate of protoxide of uranium from the peroxide. The readiest plan is to dissolve the peroxide in nitric acid, evaporate off the greater part of the excess of acid and then precipitate the uranium in the form of oxalate of the peroxide by adding oxalate of ammonia to the solution. Filter off, wash and dry this oxalate, and then ignite it in a glass tube which is closed at one end, and drawn out to a fine point at the other. When it has been kept at a red heat for five or ten minutes, and vapours have ceased to be evolved, seal up the capillary orifice and allow the tube to cool. When quite cool break it open and remove the contents (which will consist of protoxide of uranium) to a small flask. Now add pure oil of vitriol, and boil for some time, until the powder has all dissolved. Evaporate the greater part of the excess of acid off, and then add water, boil, filter, if necessary, and evaporate gently. The sulphate of the protoxide of uranium will crystallize out in the form of small green crystals. Decant the mother liquor (which will yield a further crop upon evaporation) and dry the crystals between bibulous paper. They must be kept in a well-stoppered bottle, as, like all the protosalts of uranium, they have a tendency to absorb oxygen. Our correspondent should remember, however, that the salts of the peroxide are chiefly used for photographic purposes.

F. L. P.—Glasses which have been once used and the collodion film allowed to dry on, require very careful cleaning. We do not like the common practice of soaking them in a solution of common washing soda, as it is apt to act on the surface of the glass. A little old collodion is the best thing for the purpose. Where an iron developer has been used, nitric acid should be used for the cleaning of the glasses, as without that the glass is apt to retain iron stains. For new glasses, and old ones which have had the films removed, spirits of wine and Tripoli mixed to the consistency of cream, answers the purpose of cleaning very well.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 154.—*August* 16, 1861.

"THE PHOTOGRAPHIC NUISANCE."

The phrase which heads this article is not ours; but one which we regret to say is becoming common in the public press, as designating a public annoyance which has sprung up and become rife within the last few years, to the disgust and mortification of all interested in the progress and dignity of photography.

There are few things in the world which are not the victims at times of parasitic or fungous growths, which at once mar, deform, and impoverish whatever they batten on. The weeds spring up and destroy the flowers; the tares entangle themselves with and impoverish the wheat; a rabble of plunderers hangs on the outskirts of every army; privateering is not entirely abolished among civilised nations. There are black sheep in every flock; and scoundreldom has found representatives in the church, at the bar, and amongst the medical and other learned professions. It is not surprising, then, that an art so beautiful, so popular, and so facile as photography should have been quickly inundated, and surrounded, and well nigh strangled, by a mob of "needy villains," whose only qualifications for obtaining a livelihood in any form consist in the completest incapacity, added to the most unscrupulous impudence. The fatal facility with which something may be done in the production of an image, the still more fatal "cheapness" at which a certain class of apparatus and material is vended, together with a culpable credulity and insane anxiety on the part of the public for "cheap and nasty" portraiture, has given opening and temptation to become "photographic artists" to men who would be a disgrace to the meanest mechanical calling. Some of these are detected from time to time in the production of filthy obscenities, whose hideous reality has far surpassed the most salacious limnings of the most prurient imagination, in times when the pencil only could be devoted to such polluted purposes. At other times they are found inveigling the unwary into portrait dens to be *done* in a double sense—caricature and extortion being combined in one transaction. "These cheap photographers," remarks a daily contemporary in an article we reprint in another column, "are many of them the very scum and offscourings of humanity—fellows who have not wit enough to be skittle sharpers, and not courage enough to be prize-fighters, and who find in the photographic 'studio' a convenient locality for the display of their low and clumsy arts, and the more dangerous display of their inborn knavery and philosophy."

The remarks we have just quoted are suggested by a case recently brought before the Marlborough Street Police Court, and which, we regret to add, is not a solitary one. The record of the case in the public prints stands as follows:—

"The Photographic Nuisance.—William Pimms, the keeper of a photograph portrait-place in Oxford Street, was charged with the following assault:—Mrs. Catherine Anthony, the wife of a pay sergeant of the Fusileer Guards, Wellington barracks, said she went into the defendant's shop in Oxford Street, about twelve on Saturday, to have her portrait painted for a brooch. She did not have one painted for her brooch, but had a smaller one done, and she afterwards objected to it, when she was told that it would be all right when it was dry. She afterwards returned and said she wanted her money back or a fresh portrait, and after a few words the defendant struck her on the head, rendering her insensible, and then tore up the portrait and pushed her down stairs; and the defendant's 'door man' also attacked her and damaged her clothes, and she felt certain that, if she had not been rescued, she would have lost her life. The defendant then pushed her down Oxford Street, and gave her two severe blows in the mouth.—Defendant (who insinuated that complainant was intoxicated) said she went away well satisfied with her portrait, and afterwards came back, and began 'cutting away.' He did give her a shove, and his hand might have gone in her face.—The magistrate said he had no doubt the defendant had used a great deal of unnecessary violence. It was a gross outrage on a respectable female, and defendant had not mended his case by insinuating that complainant was intoxicated. He had no doubt done that to create a prejudice. The complainant might have been a little unreasonable, but there was nothing to justify defendant's violence. He (the magistrate) was bound to protect the public. The defendant was justified in taking steps to remove a person, an objectionable person, from his premises, but not to act as he had done.—The defendant was then fined 5*l*., or imprisonment in default.—The defendant paid the fine."

Every professional portraitist is but too well aware that sitters are often unreasonable, and sometimes very provokingly so; but this can be no reason for even rudeness, still less for a disgraceful assault. Every respectable photographer is aware that trying as it may be at times to the patience, it is his interest at times to yield to, and always to treat with consideration the wishes and tastes, and even the caprices of his sitters. We may mention an illustration of the mode of dealing in such cases occuring in the practice of one of our first professional portraitists. A lady had sat for a portrait in the absence of the principal. The lady was fastidious, and the operator was patient. In turn every possible view of the face had been tried: right-side, and left-side, front, three-quarters, and profile, and almost every modification between; but the lady was dissatisfied, and resolved to try again next day when the principal would be at home. Presenting herself next morning and explaining the case, she was blandly received by Mr. M———, who had heard all particulars from his operator.

"Be so good as to take a seat here madam," placing a chair with its back to the camera.

The lady, wondering, did as she was desired; Mr. M. then proceeded gravely to place the head rest to the forehead instead of as usual to the back of the head. Having focussed, and put the plate in the camera, he said,

"Now, madam, if you will be so good as to remain quite still for a few moments—"

"Why, Mr. M., you are about to take the back of my head!" exclaimed the lady.

"Precisely so, madam. That is the only change now left for us. I have seen the pictures taken, they are all excellent Daguerreotypes, and very good likenesses. Every possible view of the face has been tried, our only chance of pleasing now, is by trying a portrait in which the face will be entirely absent."

The artist was polite and good tempered, and the lady, not entirely unreasonable, was struck with the ludicrous position: with a laugh she asked permission to see the rejected pictures of yesterday once more, and eventually selected several of them to be finished and paid for.

To return, however, to the disgraceful state of things of which the case at Marlborough Street affords an illustration. How is it to be remedied? Every respectable photographer is concerned in the removal of such a nuisance, which sullies the name of the art, and degrades the character of the pro-ession. We must confess that we are somewhat at a loss to make a suggestion on the subject. We do not imagine that we address any who are in any way associated with these Pariahs of the profession. We cannot reach them, nor do we imagine we could influence them. The whip of the law is the only means, we fear, of keeping them in check. One fruitful source of the evil is the "touting" or "doorsman" system. Without a "doorsman" to allure the victims these dens could not exist. If door touting could be abolished, this systematic photographic swindling would soon come to an end. We fear that in some cases even respectable photographers have been driven by the tide of competition to fall back upon this discreditable mode of inducing custom. We wish we could induce such, if there be any amongst our readers, to taboo such practice, and let it be abandoned to the Arabs of the profession, so that the public might be given to understand that no respectable photographer kept a touter, and if they then visit such places, they take all risks of extortion and personal injury.

Another evil contemporaneous with the nuisance of which we are speaking, and an important adjunct to it, is the Sunday trade. We have reason to believe that without their Sunday trade many of these dens must close. That is their harvest time: then victims are plentiful and are dressed for the sacrifice. Then it is that their competition tells most heavily against the respectable, middle class, fair-priced photographer, who has, in accordance with the beneficent custom of Christendom, made the seventh a day of rest. We are the sworn foes of intolerance, and utterly deny the right of the law to interfere in questions of conscience. But we must confess that we should scarcely regret to see the law relating to Sunday labour, although an enactment born of intolerance, put in force in regard to touting photographic dens, which in some parts of the metropolis are nothing short of a public nuisance in their indecent clamour. We should regard it as for once getting the use of a bad law in aid of public decency and fair play—fair play to the respectable photographer more than to the public victims, who at present we are less concerned about.

And we must add finally, that the public themselves are much concerned in the maintenance of this nuisance, against which the public press has so strongly protested, and against which we protest with as unmitigated vehemence, but more in behalf of the art and its friends than of the public. A demand creates a supply: a rage for cheap portraiture has created the supply in the form it has assumed. The public should remember that a photographic portrait does not represent simply a piece of glass, a collodion film, and an infinitessimal portion of silver; or a piece of albumenized paper, a minute trace of silver in some form, and also a little gold or sulphur. It does or should represent so many years of experience, a considerable amount of scientific knowledge, and a fair share of artistic taste and skill, together with the use of costly appliances. And to imagine these can be secured for a sum that can be counted in pence is simply a piece of the wildest folly: folly which only meets a fair reward in the fast-fading caricature which is the legitimate issue of such establishments. If photography be a mechanical art, as her Majesty's Commissioners have decided, and as some of its professors have endorsed, it at least requires skilled workmen, who are worthy of fair wages, as M. Silvy himself would admit. Let the public, then, protect themselves, if they don't honour the art; and let them pay a fair price, and avoid the den of the miscalled *cheap*, touting portrait manufacturer.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Hydriodic Acid.—This acid is very similar in character and chemical composition to the two former acids which have been treated of. There are several ways by which it can be prepared. One of the most common is to mix together in a small retort 10 parts of iodide of potassium with 5 of water. The iodide of potassium should be finely powdered, and the water added until it is of a pasty consistency; 20 parts of iodine are now to be added, and when the materials are well mixed together, 1 part of phosphorus is to be cut up, under water, into small pieces and dropped in one at a time. Hydriodic acid is evolved in abundance, in the gaseous state. It must be conducted by means of a tube connected with the neck of the retort by a cork, into a bottle of distilled water standing in a vessel of cold water. The gaseous acid will be absorbed rapidly by the water, and will form the ordinary liquid hydriodic acid. If the evolution of the gaseous acid does not proceed with sufficient rapidity, the retort must be gently warmed by plunging it into hot water for a minute or two; if, on the other hand, the gas is liberated with too great violence, the vessel must be plunged into cold water. This is a very economical way, as the whole of the iodine, both from the iodide of potassium and that in the free state, is converted into hydriodic acid, phosphate of potash being formed.

Another plan which is frequently recommended in works on photography is to suspend iodine in water, or to dissolve iodine in a dilute aqueous solution of iodide of potassium, and then to pass a current of suphuretted hydrogen gas through the solution; the iodine displaces the sulphur and unites with the hydrogen, forming a dilute aqueous solution of hydriodic acid with precipitation of the sulphur. If nothing has been added to the water but iodine, the solution need only be filtered from sulphur (provided it has no smell of hydrosulphuric acid), when it can be used; but if iodide of potassium has been employed as a solvent for the iodine, the aqueous solution will have to be distilled. If the liquid smells of sulphuretted hydrogen, this can be got rid of by shaking it up with a small quantity more of iodine. Since hydriodic acid dissolves iodine easily, a very strong solution of the acid can be prepared by alternately dissolving iodine in the solution and then passing sulphuretted hydrogen through until the deep brown colour is removed. This, however, is not a good plan to prepare the acid for delicate photographic work, although it is very easy and convenient. It is always liable to contain some sulphur compounds from which it is difficult to purify it. We think the best plan is to adopt a suggestion recently made by M. Personne, and prepare it by the action of phosphorus and iodine on water in the manner recommended in the first process above given, using, however, amorphous instead of normal phosphorus. It is enough to place a sufficiently large quantity of amorphous phosphorus in a tubulated retort with a glass stopper, to cover it with a layer of water, and to add the proper amount of iodine, when, by the aid of a slight degree of heat, a regular current of gas is obtained perfectly free from iodine vapour, which may be conducted through water and absorbed in the usual manner. Another very convenient plan, which may be useful to some photographers, in the absence of distillatory apparatus, is to dissolve a known weight of iodide of barium in water and then to decompose this by adding an exactly equivalent quantity of sulphuric acid. By filtration from the sulphate of baryta an aqueous solution of pure hydriodic acid will be obtained.

As prepared by either of these methods, hydriodic acid is a strongly acid, colourless liquid, fuming in the air when strong, and having a sharp, suffocating odour. The concentrated acid is very heavy, having a specific gravity of 1·7; when of this strength it boils at 126° C, and distils over unchanged. By boiling, a weaker acid becomes stronger, and a strong acid weaker, the ultimate strength being an acid of the above specific gravity. Hydriodic acid when exposed to the air gives off hydrogen to the oxygen of the atmosphere and become deeply coloured by the liberated iodine. As the decomposition proceeds the iodine is gradually precipitated in the form of beautiful large crystals, the supernatent solution being scarcely anything but pure water. Hydriodic is decomposed by many other agents besides the atmosphere. Oil of vitriol added to it separates iodine with formation of sulphurous acid. Iodic acid, or an iodate, likewise instantly decompose each other with liberation of iodine; nitric acid, as well as other oxygen compounds of nitrogen, also liberate iodine.

The liberation of iodine from old collodion is a subject closely connected with that of the decomposition of hydriodic acid. There are several ways in which this colouration of the collodion by iodine can take place; if the cotton or paper contains the slightest trace of free nitric or sulphuric acid, owing to its not being thoroughly washed (and this is not so easy to accomplish as is generally supposed), the liberation of iodine in the collodion is almost certain to take place a short time after its being made. It is also possible that there may be a gradual decomposition of the zyloidin itself, and consequent liberation of the iodine by this means, with formation of nitrates or nitrites; but the most likely cause is the following:—The ether gradually absorbs oxygen from the atmosphere, and is converted into acetic acid; this, by its superior affinities, reacts on the iodide present, converting it into acetate, with liberation of hydriodic acid, whilst this latter, under the influence of the atmospheric oxygen, is gradually converted into water and iodine. The reason which has induced us to adopt this explanation of the colouration of old collodion, is that bromised collodion does not undergo any change of colour however long it is kept. Now if the former agencies were at work there is no reason why bromine should not be liberated from a bromide, as well as iodine from an iodide; but on the latter supposition no change can take place, the affinities of acetic acid being insufficient to displace hydrobromic acid.

Similar impurities are likely to be present in commercial hydriodic acid as in hydrobromic acid. It may thus contain *phosphorus* from the mode of its preparation. The method of detecting this is the same as in the case of hydrobromic acid, viz., oxidation with nitric acid. *Sulphuric* and *organic compounds* may likewise be present, and may be detected as detailed in our last chapter. Free *iodine*, which is a very frequent impurity, is at once seen by its colour; it is best removed by agitation with a little zinc or cadmium, and then distilling, the iodine uniting with the metal will remain behind. Another plan is to add a drop or two of sulphuretted hydrogen water to the coloured acid, shaking after each addition until the colour just disappears. Too much must be avoided or the liquid will smell of it. If this is the case the excess of sulphuretted hydrogen must be removed by heating the acid to the boiling point. Another impurity which may be present in commercial hydriodic acid is hydrocyanic acid or cyanogen compounds. Some samples of iodine have been found to contain iodide of cyanogen, and this compound would in the process of preparing the hydriodic acid as decomposed into that and hydrocyanic acid. This is not a very likely impurity; but as it would be productive of great injury if it were present, it will be advisable to test for it. This may readily be done; add a little sulphide of ammonium to the suspected acid and boil, this will convert the cyanogen compound into sulphocyanide of ammonium, which has the property of communicating a most intense blood-red colour to persalts of iron. If therefore the solution, after the excess of sulphide of ammonium is boiled off, gives a red colour, or even a pink tinge, upon addition of a drop of solution of perchloride of iron, it may be considered as a proof that a cyanogen compound has been present.

A NEW PHOTOGRAPHIC PROCESS.

By James Eugene Balsamo, Professor of Natural Philosophy, Lecca, Italy.

Extrusted, during the year 1859, with the direction of laying the submarine cable between Italy and Turkey, in the Ionian Sea, I experienced the want of being able to reduce the generators of electricity to the simplest possible expression. I have already published some of the results obtained, but I now propose to describe a new photographic process, which is the fruit of my electrical experiments. During the working of the various piles I had contrived, I discovered that hydrochloric acid enjoyed the property of dissolving phosphorus, which it afterwards abandoned, in a flocculent state, under the influence of the action of light. Thereupon I conceived the idea, that here was one of those substances which, although naturally inert to light, nevertheless undergo a sort of molecular orientation on the part of the phosphorus precipitated in the hydrochloric acid; and experiments rigorously pursued, together with long observations, have demonstrated that there is not any soluble salt which can resist the modifying action of light, in this phosphor-hydrochloric solution. But the salt to which I give the preference, both on account of the facility with which it may be everywhere obtained, and on account of its low commercial value, as well as for its sensitiveness—is acetate of copper. I proceed in the following manner:—I prepare my hydrochloric solution by digesting phosphorus for a long time in hydrochloric acid, at the ordinary temperature, or if required in haste, at a temperature of 180° to 200° F. The older this solution becomes, the greater its photogenic properties. After thus saturating the hydrochloric acid with phosphorus, I dilute it with acetate of copper until the colour of the liquor becomes of a deep olive-green. This cupro-phosphor-hydrochloric solution is poured into a glass or porcelain dish, and a sheet of paper is immersed in it during three or four minutes; then another sheet is added, and so on, until a sufficient number of sheets is immersed, which must be separated and turned from time to time, so that the solution may fully penetrate the pores of the paper.

After five or six hours the paper will have thoroughly imbibed the solution, and the sheets are carefully separated, avoiding rents and creases, and then hung up to dry sheltered from dust and access of light. It is an essential condition to the sensibility of the paper that it be quite dry; for it becomes very hygroscopic after being submitted to the sensitizing bath, and the least presence of moisture diminishes its sensibility.

When it is desired to take pictures on this paper, a sheet of bibulous paper must be placed at the back, to absorb the moisture disengaged under the influence of the calorific rays. The paper remains under the negative until it acquires a grey tint. It is then withdrawn from the printing frame, and submitted during the space of five minutes to the vapours of sulphuretted hydrogen, which possesses the property of attacking those parts of the proof which have been acted upon by light. The image being thus fixed is washed in plenty of water, which removes all the salt of copper from the paper, and the picture appears with the greatest clearness of contour and detail. To render it permanent, and to tone it of an agreeable colour, the proof is soaked in a solution of nitrate of bismuth. But as an insoluble subsalt is formed in the water, a little nitric acid must be added. The more the solution is diluted, the longer the proof must remain in it, and the greater amount of detail will be eliminated.

In the bismuth bath, a real molecular substitution of bismuth for copper takes place; and at the expiration of a certain time, the liquid becomes of a green colour, due to the nitrate of copper which is formed, and bin-oxide is also found deposited.

The pictures obtained by this process are indestructible, for an external coating of oxide of bismuth is formed, and neither chlorine nor any other transforming substance remains. Chlorine, which is one of the most active photogenic elements, is also a de-hydrogenizing agent *par excellence*, and its oxydizing effects are an indirect consequence. From this arises the transformation of the metallic sulphides of the proofs into colourless sulphates. If we substract (as can be done) the chlorine from the pure photographic proofs in a salt of silver, we shall have pictures more permanent and less sensible to the causes that can efface them, as I have proved by experiment.

The photo-chemical phenomena manifested in my process are the following:—Light acts directly upon the phosphorus, which, in the molecular disturbance, reduces the salt of copper and brings it to the state of bin-oxide. For, if instead of fixing the picture by sulphuretted hydrogen, we soak the proof in water, on removing it from the printing-frame, we shall see the image appear by transparency, and formed entirely by phosphorus. As I have before said, copper in the state of bin-oxide is very easily reduced by hydrogenized matters, from whence it results that a very short exposure to the vapours of sulphuretted hydrogen suffices to fix the image in a state of sulphide. But as the bi-sulphide of copper, which is very unstable, passes to the state of sulphate, and finally is effaced. I replaced it by bismuth. Thus the bismuth, in being substituted for the copper, re-composes the image, fixes and tones it; and the colour will be more or less deep, according as the sensitized paper is rich in cupreous salt, the duration of the exposure in the printing-frame, the intensity of the light, and the strength of the bismuth bath. If we wish the toning to be deeper, the picture may be afterwards immersed in a weak solution of nitrate of silver, which is not altered, but plays the part of a negative metal to the bismuth. The curious phenomena I have observed in many metallic salts during my photogenic experiments will form the subject of a future communication.

THE COLLODIO-ALBUMEN PROCESS.

BY JAMES MUDD.

I will not argue the question of the comparative merits of the various dry processes, or assume for the collodio-albumen a place higher than some others. I believe that there are half-a-dozen of tolerably equal merit, and that any one of them may be made to yield results equal to the others if carefully worked out. The process under our notice has many admirers, and is successfully managed by many photographers. In some hands, however, it does not answer. To those who have failed, perhaps the following description of the process may be of some use, although I fear I am only repeating much that has been said before.

It is important that the plate should be well cleaned. There are various methods of doing this; but as this is necessary in all processes, photographers will know how to perform this simple operation. Coat the cleaned plate with collodion in the usual way. After allowing the film to "set" well, sensitize in the ordinary nitrate of silver bath. If the collodion should give a very thick and creamy film, it must be reduced by adding ether. After sensitizing, the plate must be well washed. This is done best by having two large water dishes with a tap running into each; into the first of which the plate should be immersed, moved about, and then removed into the second. A third dish is required containing a weak solution of iodide of potassium and water, about one grain to the ounce of water. Place the plate in this solution two or three minutes, gently moving the dish the while. Rinse with tap water, and drain a minute.

The next operation is pouring on the iodized albumen. It is made as follows:—

To the whites of 10 eggs add—
50 grains iodide potassium
10 ,, bromide ,,
100 minims liquid ammonia
$2\frac{1}{2}$ ounces water.

Dissolve the iodide and bromide in the water, then add the ammonia. Mix all together with the albumen, and beat the whole into a froth. Let it settle. It is then fit for use.

While the plate is still wet from the washing, and after it has drained a moment or two, pour over its surface the albumen. Pour off again. Repeat this twice. The same albumen may be used for two or three plates, but becomes too limpid, by mixing with the water from the plates, to use for more. It should be thrown away, and a fresh quantity obtained. Now allow the plate to drain five or ten minutes; then dry it rapidly before a clear bright fire, and make it quite hot.

The plate in its present state is not sensitive to light and will "keep" for an indefinite period. I have never known them to deteriorate in the slightest degree, and have frequently used them twelve months old. This keeping-quality is convenient, as it enables the photographer to prepare, during the winter months, a stock of plates for the summer season. To make the plate sensitive, it is only necessary to dip it for one minute into the aceto-nitrate bath:—

40 grains nitrate of silver
$\frac{1}{2}$ drachm glacial acetic acid
1 oz. water.

Before immersing, however, warm the plate slightly at the fire, or in any convenient way. After taking it out of the bath, drain a moment, and then wash as before in the dishes and finally under the tap. Common spring water will do. It is not necessary to use distilled water either in the preparation, or in the development of the plates. After washing, drain and place on blotting-paper to dry. They may be dried artificially, but will dry without heat in about ten minutes.

Plates so prepared will keep good in cool weather six or eight weeks, but in July or August it is better not to trust them longer than a fortnight. In hot weather there is a tendency to turn red under development if kept sensitized longer.

And now as regards sensitiveness and exposure. Compared with wet collodion these plates are five or six times less sensitive.

It is difficult, in figures, to give a correct idea of the time, so much depending upon lens, subject, aperture, &c. One or two trials will decide this better than anything I can say. It may be some guide, however, to compare it with other dry processes, the Fothergill, honey, gelatine, and others. It is quicker than any of those I have named, and certainly stands next to wet collodion in sensitiveness.

The development of the latent image is the most important operation in this process. It is slow, but on that account very manageable and entirely under control. My method of developing at present is with pyrogallic acid. I have seen, however, good results by gallic acid development. To develop with pyro, take the exposed plate, and after placing it upon the stand, pass over the surface a little common clean water; then take a plain pyro solution without acid, say two or three grains to the ounce of water, and pour it on the plate. This mixture must be made just before use, as it does not keep without acid. The sky and high lights will appear almost immediately, and ultimately, without either silver or acid, the whole picture comes out. It now requires intensity. Now take—

Pyro ... ... 2 grains
Citric acid ... ... 1 grain
Silver, two or three drops of 20-grain solution,

and pour on the plate. If necessary, add more silver until sufficient intensity is gained.

During the development it is more than probable that the surface may be marked by streaks or stains; or a deposit may cover the whole plate. If this should occur, stop the development, wash with water, and with a piece of fine cotton-wool rub away these defects, and go on again with the development. The horny surface of the albumen covering enables you to do this without fear of damaging the negative. This is the great advantage the process has over every other. The Fothergill, gelatine, and other processes will not bear long development. If it is prolonged, a deposit falls, and the softness of the film does not allow it to be removed. The collodio-albumen plate can be developed for hours or days, because, though the deposit falls, it can be wiped off again and again. This is an immense advantage when the picture is under-exposed, as it can be frequently brought out by long development.

To know when a negative is sufficiently developed is a nice point; and it is very easy to be deceived in the comparative darkness of the operating room. A negative always looks a great deal more intense in the room than it does when brought to the light. This must be allowed for. It is an excellent plan to have a good negative in the room with you, in order to compare with the one you are producing. Do not judge of the merits of your picture by the blackness of the sky, but by the details of the picture itself. A really good negative will rarely have a dense sky.

Warm solution has been mentioned lately as useful in pushing the development. It ought only to be used, however, when the picture is under-exposed. I have always used it in the winter months, when the temperature of the water was low, and in pictures which would not appear with cold water.

To develop with gallic acid:—Take the exposed plate and put it, face upwards, into a glass or dish, with a sufficient quantity of a saturated solution of gallic acid to cover it. When it has remained five or ten minutes, add a few drops of 10-grain silver solution, and mix well in the dish; the picture will gradually appear. When all the details are out, add more silver till the development is complete. This is a slower method than the other; but several dishes, each containing a plate, may be attended to at the same time.

Fix in hyposulphite of soda, about six ounces to the pint of water. Cyanide of potassium must not be used for this purpose.

Such, then, is the process as at present used by myself in the production of my landscapes.

In connection with this subject I cannot forbear mentioning the name of a very successful operator here in Manchester, Mr. Wardley, who has worked the process with me for several years, and to whom I owe many valuable suggestions, not the least of which is the plan of first using the developing solution without acid.

NEGATIVES BY POSITIVE PROCESS.

[The following communication does not profess to detail any new process; but is merely a statement of what has, in principle at least, before been published. It has, however, this advantage, that it has the exact formula and mode of manipulating by which the writer produces successful results; and this is, after all, the best recommendation which any process can possess. The precise collodion which was named by the writer is not to be obtained now, but any *good* bromo-iodized collodion wlll answer the purpose. It is desirable, however, that it should give a moderately intense image to commence with, that is, by the action of the iron developer only.]

Dear Sir,—Acting according to the promise I gave you last week, I now send you the details of the process by which the negative, a proof of which I sent you, was taken, and which is the one I always use with success.

As to collodion, I always use a positive one, which gives, when taken from the bath, a good, even, and creamy film, and is free from waves or other irregularities, and one which will bear washing. * * * *

The bath should be composed of the *pure* recrystallized nitrate of silver, and not the commercial crystallized sold for printing, which if used would be a never-failing source of fog and stains. Recrystallized nitrate of silver 40 grains to one ounce of distilled water. In making an entirely new bath, I generally dissolve 3 ounces of silver in 33 ounces of distilled water; then coat a large plate with collodion on both sides and let it remain in the bath a few hours to saturate the solutions with iodide of silver. After each day's work is completed, I return the solution to the bottle, and wash out the bath. This prevents the necessity for repeated filtering and consequent loss of solution. After the bath has been saturated with iodide of silver, as before described, it is possible that on taking a picture the bath may now and then fog. To remove this tendency, I keep in a separate bottle a diluted solution of pure nitric acid, in the proportion of nitric acid one drop, distilled water one ounce. One drop of this diluted solution of nitric acid added to a bath of about 33 ounces will generally, if the silver be quite pure, make it yield good results. In no case do I add even this small proportion of acid to the bath when good results can be got without its use.

A bath thus prepared will work equally well for positives or negatives with the same collodion.

Expose just half as long again for a negative as for a positive. Then develope with a solution of proto-sulphate of iron prepared as follows: iron, 2 drachms and I scruple; water, 15 ounces, adding I drachm of glacial acetic acid to an ounce of the above iron solution immediately before using. I get all the details well out, and as much intensity as you can get at this first stage, by throwing the solution on and off the plate, as in developing a negative with pyrogallic acid.

I now wash well and fix with cyanide not too strong. Intensify while the plate is wet as follows: water, 15 ounces; pyrogallic acid, half a drachm; citric acid, half a scruple. Pour a little of this solution of pyro over the plate so as to get it to flow evenly first; then add two or three drops of a 30 grain nitrate of silver solution to an ounce of the above solution, when any amount of intensity can be gained. Pictures so developed are not so hard, having such violent contrasts of light and shade as those taken with an intense negative collodion, and developed with pyro and silver.

It may sometimes happen, under certain conditions of light and temperature, that some little difficulty is experienced in getting sufficient density with the above; when such is the case, after well washing to free from pyro, pour over the plate a saturated solution of bichloride of mercury; wash again, then pour over the plate a solution of iodide of ammonium, two or three grains to the ounce, exact strength not important. If iodide of ammonium is not at hand, iodide of potassium will do, but I prefer the former when I resort to this, which is not very often. I would not counsel the use of the bichloride of mercury and iodide in any case where it can possibly be dispensed with. It is very well as an occasional makeshift, but not for constant and continual use.

After the plate is dry, varnish with the Soehnee varnish. If it would be acceptable I will another time give you my experience with hot developers for winter work, as well as a few words about glass positives, with developers of various strengths.—I remain, dear sir, yours very truly,

T. S. Swatridge.

Yeovil.

SOLAR CHEMISTRY.

Light and heat are so closely allied to each other and to all natural objects, and both are so intimately connected with man's existence and happiness, that every discovery regarding either is of the highest value, not merely to science, but also to manufactures and the arts. By those who devote their lives to the study of science, every new fact is regarded as, in itself, another treasure gained. Those, however, who are engaged in commerce or in any industrial pursuit, are apt to measure each acquisition by its practical value, and the immediate addition it makes to human wealth. To the attention of both these classes, the late discoveries regarding light recommend themselves. By glancing at their connection with previous discoveries we shall best be enabled to appreciate their importance and practical value.

About 1666, Newton resolved white sunlight, by means of a prism, into seven primitive colours, and in 1704 he gave his discoveries to the world in his splendid work on Optics. In 1808 Wollaston first noticed in the prismatic spectra, dark lines, the positions of which were so accurately determined twelve years afterwards (in 1820) by

Frawnhofer, the optician, that they are sometimes called Frawnhofer's lines. The latter observer counted 600 of these dark lines or breaks in the coloured spectrum, and Sir David Brewster, in 1833, by his experiments with nitric oxide, succeeded in counting more than 2,000 lines. At certain seasons of the year, some of these lines are not discoverable in the spectrum, a phenomena attributed by Sir David Brewster to different altitudes of the sun, and to the different absorption of the rays in their passage through our atmosphere. In the reflected light of the planets and their satellites, we discover, as might be expected, all the peculiarities of the solar spectrum. But when we apply the same method of analysis to the light of the fixed stars we find strange, and hitherto unexplained, differences. Frawnhofer called attention to the fact that even in those fixed stars which have an equal and perfectly white light the dark lines are not the same; probably showing that different metals predominate in the gaseous envelopes of different stars. "The dark lines," says Humboldt, "in the spectrum of Sirius differ from those of Castor and the other fixed stars. Castor likewise exhibits different lines from Pollux and Procyon. The light of incandescent solid bodies and the light of the electric spark also exhibit great diversity in the number and position of Wollaston's dark lines."

The mystery of these dark lines in the spectrum remained unsolved long after it was known that every simple substance could be distinguished by the colour of its flame when subjected to prismatic analysis. Brewster discovered that the flame of alcohol diluted with water, consists chiefly of homogenous yellow rays. Herschel discovered that sulphur, when burning intensely, gives a light of similar colour. In 1826, 1833, 1834, 1836, Mr. H. F. Talbot directed public attention to the same subject, and distinctly announced, in 1834, the truth that "optical analysis can distinguish the minutest portions of two substances, as lithia and strontia, from each other with as much certainty, if not more, than any other known method." Professor Wheatstone, in 1835, read a paper "On the Prismatic Decomposition of the Electric Voltaic, and Electro-Magnetic Sparks," at the meeting of the British Association in Dublin, directing his attention, however, to the bright lines, and concluding with the significant remark, that "the peculiar luminous effects produced by electrical action on different metals depend on their molecular structure." He also added, "We have hence a new optical means of examining the internal mechanism of matter, in addition to those which Sir D. Brewster and other philosophers have already placed at our disposal." In 1845, Professor Miller read at Cambridge, before the British Association, an account of his experiments and observations on dark lines in the prismatic spectrum produced by the passage of light through coloured vapours and gases, and from certain coloured flames. In this valuable paper he gave a large number of most interesting facts, and almost anticipated, by nearly sixteen years, the discovery for which we are indebted to Kirchhoff. He then stated, in regard to the absorptive action of the sun's atmosphere, "that if solar light be transmitted through a flame exhibiting well-marked black lines, these lines re-appear in the compound spectrum, provided the light of day be not too intense compared with that of the coloured flame. It would, therefore, appear that luminous atmospheres exist, in which not only certain rays are wanting, but which exercise a positive absorptive influence upon other lights." The full meaning of this statement was, however, not perceived at that time. Even with such a plain statement of the truth that certain luminous atmospheres absorbed certain lights, the dark lines of the solar spectrum remained a standing puzzle. And it was only last year that Kirchhoff proved clearly that these dark lines are caused by the absorbing influence of certain constituents of the solar atmosphere, and that these constituents are the metals—iron, magnesium, nickel, chromium, potassium, and sodium.

But in addition to these discoveries of metals in distant worlds, this method of spectrum analysis has been applied to the discovery of new metals on our earth. In examining the spectra of the alkalies obtained from certain mineral waters, Bunsen observed two bright blue lines, which gave evidence of the presence of a new metal. This new metal—cæsium—has been obtained separate; also others, such as rubidium and thallium; and as this path has only now been opened, we may anticipate, as the result of further researches, many valuable discoveries. At present we are justified in stating, as a general law, that every simple substance in nature—either upon the earth, or in the sun, or in the remotest regions of space—has its peculiar bands of light. its own colour and shade, which distinguishes it from every other; and that it emits, radiates and absorbs its own colours exclusively. There is a mysterious but most intimate connection between the atoms of the etherial medium, whose vibrations give us sensations of light and colour, and the atoms of those elementary substances which we can handle and weigh. Though the nature of this connection may long remain unknown, new proofs of its reality may be expected to accumulate daily.

To assist in exploring these new fields, science calls art and industry to its aid, and new instruments are invented, and new manufactures originate. Already five or six spectroscopes, or spectrum analysers, are in the market. Whether this new invention will prove as valuable an aid to science as the telescope, polariscope, and microscope, we know not; but who can limit the powers of an instrument which is equally applicable in detecting the presence of the one hundred and eighty millionth part of a grain of matter in the dust beneath our feet, or the metals floating around the sun, or around distant stars, whose light travels for thousands of ages before reaching our planet? Reasoning from known facts regarding the polarization of light, and by the use of Arago's polariscope, we can ascertain whether the source of any light is solid, liquid, or gaseous. Applying this method to the sun, we obtain clear evidences of its being a solid nucleus, surrounded by a glowing, gaseous atmosphere.

Reasoning from equally well-known facts regarding the refraction, radiation, and absorption of different colours, and using the simple prism which proved so valuable in the hands of Newton, we have analysed this gaseous atmosphere as the metallurgist separates ores, or the chemist resolves into its simple elements any of the compound substances common in the laboratory. At present, however, this science of solar chemistry is only in its infancy. We know not yet why the light of the sun is white; why the fields and forests in summer time are green; why the sky is blue; why the planets and stars vary in colour—some white others yellow, or red, or green, or blue. Even the simplest facts regarding light, heat, and the substances generally called imponderable, are yet unsolved mysteries. We have only commenced to cultivate the new field, and know as little regarding the number or variety of the instruments that may be required in prosecuting our researches as of the rich fruits it may yield.

The lectures of Professor Roscoe and Professor Tyndall, recently delivered at the Royal Institution, give so clear an outline of the discoveries of Bunsen and Kirchhoff, and their connection with the previously-ascertained truths of optical science, that we confine our remarks to the history of the discovery, and its importance. They have questioned light, and compelled it to tell the story of its birth. They have given us visible, if not tangible proof of the unity of the solar system. Not merely as proved by Newton are all planetary bodies bound to the sun by the law of gravitation—they are all composed of the same elements. Probably all the simple bodies which chemists have discovered upon the earth exist also in the sun, and in all the planets of the solar system, though, as Newton suggested, "variously concocted." The conjectures of the ancient philosophers of India and Greece are thus returning to life. We have revived and established the doctrine of Aristarchus of Samos, that the fixed stars and the whole planetary system are of one and the same nature.—*Mechanics' Magazine.*

PHOTOGRAPHIC DENS AND "DOORSMEN."

(From the *Daily Telegraph.*)

There are functionaries called inspectors of nuisances, whose duty it is to rout out and report the execrably filthy hovels which sin against the provisions of the Common Lodging House Act; to take care that laystalls and shambles, cesspools and sewers, gasworks and bone-boiling houses, tallow manufactories and glueworks, are not unnecessarily offensive to the public nose and the public lungs; who seize upon diseased meat, and in a measure perform the functions of the old "aleconners" and ward-jurymen. It is true that they no longer chop up fraudulent weights and measures before the door of the offending tradesman, pour sophisticated beer and adulterated milk into the kennel, administer a round dozen to chapmen or costermongers whose fruit is bruised or whose fish is stale, and nail the ears of dishonest bakers to their own doorposts. Would they did! to say nothing of the benefit that might accrue to the community at large if the inspectors of nuisances were permitted to maintain a pillory, stocks, and whipping-post of their own at some convenient spot—say in the vacant enclosure round St. Paul's Cathedral—and there administer summary punishment, or expose to public view the swindling shopkeepers who sell worthless or damaged goods—the insolent omibus-conductors and extortionate cab-drivers, who fleece and insult ladies—and the abominable little half-naked ruffians who turn "cart-wheels" in the mud, to the terror of horses and of nervous passengers. Such a rough and ready justice would be contrary to our notions of civilization, but the substantial benefit derived would be large. What a comfort would this summary castigation be to the defrauded customer who has bought a sleezy half-cotton for a glacé silk, or a catskin muff for a chinchilla! How good men would rejoice to see the grocer who sands his sugar and birch-brooms his tea squatting in the stocks, or the insolent "cabby" who has demanded half a crown for a shilling fare wriggling his head in the penal collar of the pillory. Inspectors of nuisances have no power to impose inflictions such as these. They do their duty, as an occasional police-court case shows; but their operations are, after all, of a very lame and limited nature, and the public have got into the habit of mixing them up with the district surveyor and the gentleman who comes to look after the gas-meter or the cistern, and their jurisdiction is questioned and their functions cavilled at, till a general impression arises that they are but a little better than excisemen, and decidedly inferior to the collectors of water-rates.

In the streets of London there are at present some patent and visible nuisances which call loudly for abatement, but which, unhappily—owing, we presume, to a distortion of the principle that every Englishman's house is his castle—not only inspectors of nuisances dare not meddle with, but parochial authorities seem powerless to touch. Foremost among these stands the photographic nuisance. We are, it is needless to say, sincere admirers of this delightful, useful, and humanising art; and, in its proper place, photography is capable of doing, and has done, immense service to the cause of education and civilization. In its humbler aspect, too—in its mere shape of a substitute for the craft of the cheap miniature painter and the profile cutter—we see nothing to object to in photography; and there is certainly no reason why the cook or the housemaid out for a holiday, or the policeman off duty, the lacquey anxious to see his plush and powder transferred to glass or paper, should not "have their pictures done" as well as the dashing officers and brilliant ladies who crowd the studio of a Mayall, a Watkins, a Claudet, or a Lock. But *est modus in rebus.* There is a reason in roasting eggs. There is a golden mean to be observed in the art sacred to Phœbus. When we find photography associated with the lowest ruffianism and blackguardism, and made the medium of imposture and extortion, we are apt to grow somewhat out of patience with the proprietors of popular cameras and the manipulators of "portraits for the million." We are not alluding just now to the human skunks who have turned photography into a means for the production of infamous pictures, and some of whom are even now, thanks to the late Lord Campbell's Act, expiating in the House of Correction their offences against good morals. Our censure is directed against the low dens of cheap photography, with which even the most respectable of our thoroughfares are becoming more and more rapidly infested. There is a duplicate system of ruffianism in these disgraceful places. There is the "professor," or "manipulator," or "focusser," or whatever he may call himself, who keeps in the dog-hole he terms a "studio;" who executes vile libels on humanity which he misnames portraits; who enhances the original price; who bullies women and terrifies boys and girls into buying expensive frames, or having the blear-eyed patches he has drawn from the camera coloured; and who, in default of finding dupes, or on being remonstrated with, resorts to such "manipulatory" processes as striking, kicking, and half throttling his sitters. These cheap photographers are many of them the very scum and offscourings of humanity—fellows who have not wit enough to be skittle-sharpers, and not courage enough to be prize-fighters, and who find in the photographic "studio" a convenient locality for the display of their low and clumsy arts and the more dangerous display of their inborn knavery and philosophy.

Low and degraded as these fellows are, they have associated with them even lower varieties of the "cad" species. To every one of these cheap photographic studios there is attached one or more hired bullies called "door men," whose vocation it is to prowl up and down before the portal of the unwholesome temple of black art, to thrust villanous portraits into the faces of the passers by; to make use of filthy and ribald talk to the giddy girls who stop to stare at the framed display of portraits; to exchange blackguard repartee with "the door men" of some neighbouring and rival studio; and, if need be, to assist their employers in ejecting, pummelling, and otherwise maltreating troublesome customers. In the New-cut, and before the discovery of photography, these gentlemen found exercise for their lungs, and a vent for their filth, in descanting on Saturday nights on the merits of flyblown butchers' meat and decayed vegetables, and were known as "Barkers." Two recent police cases, in one of which the complainant was the wife of a sergeant in the Guards who had been most shamefully abused and beaten by a fellow called Pimms, keeping a cheap portrait place in Oxford-street, and his "door man," show to what a height this photographic nuisance has grown, and the imperative manner in which its suppression is called for. Is there no means of proceeding against these "door men" by indictment? Can they not be punished for obstructing the thoroughfare? In common law it might be decidedly argued that every invitation to have your portrait taken, proceeding from one of these disgusting fellows, is a provocation to commit a breach of the peace. It took an Act of Parliament to put down the betting-shop nuisance. Let us trust that some mode less elaborate and less expensive may speedily be found for mitigating this atrocious nuisance of cheap and nasty photographers and their ruffiianly "door men."

Dictionary of Photography.*

Qualitative Analysis, in chemistry, designates the process whereby the constituents of a compound are determined by observing the reactions which determine their qualities. Thus, a solution is to be examined for the presence of silver. If sulphuretted hydrogen be added, and a black precipitate, sulphuret of silver, falls, that is one indication of the presence of silver. To another portion of the same solution hydrochloric acid is added, and a white curdy precipitate is formed. To half of this nitric acid is added, which produces no effect upon the chloride of silver. To the other half ammonia is added, which at once dissolves the chloride of silver. These tests would be sufficient to determine the presence of silver in the solution. This is one of the simple acts of qualitative analysis which the photographer often may be called upon to perform.

Quantitative Analysis designates the process by which, the nature of the contents of a compound being known, the

* Continued from p 380

proportions in which they are present are determined. Thus a solution having been ascertained to contain silver, the amount of silver present may be ascertained by precipitating the whole in the shape of a chloride by means of hydrochloric acid, and then carefully weighing the precipitate. Or it may be ascertained by observing exactly the amount of a solution of chloride of sodium of known strength required to precipitate the amount of silver present, and a calculation based on the known relations, will determine the amount of silver present. This is one of the most important quantitative analysis which the photographer is called upon to perform. The exact proportions and modes of proceeding have already been detailed in the early part of the present volume.

Quarter-plate.—A term used to designate a certain size of plate used in photography. In the early days of photography the largest size used for a daguerreotype plate was $8\frac{1}{2}$ inches by $6\frac{1}{2}$ inches, and this was called a whole plate. A quarter-plate is one-fourth of that size, and is in the proportion of $4\frac{1}{4}$ inches by $3\frac{1}{4}$ inches. A quarter-plate lens is a lens intended to cover satisfactorily a plate of the dimensions just stated.

Quick Action in Lenses.—The term quickness of action in lenses is used to designate the rapidity with which a photographic image is formed by them on a sensitive surface. This quickness depends upon a judicious combination of many circumstances, such as the form, colour, and quality of the glass, the number of reflecting surfaces, the focal length, and the relation of the aperture thereto. The purer the glass in colour, and the fewer the reflecting surfaces, other things being equal, the more rapid will be its action. The chief circumstance affecting rapidity is the length of focus and the amount of light admitted. The shorter the focus and the larger the aperture, the greater the quickness of action. The most rapid lens perhaps in existence is that used by Mr. Skaife in his pistol camera, in which the width of the aperture is as great as the focus of the lens. The length of focus is one inch, and the aperture is one inch. Speaking roughly, in round numbers, we may state that in portrait lenses generally the amount of full aperture is generally about one-fourth of the focal length of the lens. As a rule, and other things being equal, the length of exposure increases as the square of the focus of the lens; thus double the focus will require four times the exposure, if all other conditions remain the same. So also the exposure is increased in the square of the ratio with which the aperture is decreased, so that an aperture of half the diameter will require four times the exposure, as it only admits one-fourth as much light. These are general rules, but they are found to be materially modified in practice by a variety of circumstances.

Quick Lime, protoxide of calcium, Ca. O. Its chief use in photography is as a dessicating agent. Alcohol is sometimes distilled over it to deprive it of water. Quick lime is also used in drying boxes for sensitive paper instead of chloride of calcium, over which it has some advantages.

Quicksilver, or Mercury, Hg.—A peculiar metal which at one time was of much importance in photography, and some of the salts of which are still largely used for different purposes by photographers. The bi-chloride of mercury is the most useful, and is used for whitening positives and intensifying negatives. It is soluble in 3 parts of boiling water and in 16 parts of cold water. To effect this solution it should, however, be very carefully powdered and well agitated. It is sometimes recommended to dissolve it in hydrochloric acid, and then dilute with water. This practice is not desirable, as the acid injures the film. Chloride of ammonium added, rapidly increases its solubility and does not injure its action. In the negative it is generally converted into iodide of mercury by means of iodide of potassium, or into a sulphide of mercury by hyposulphite of soda.

Ramsden's Eye-piece, or Positive Eye-piece, is a combination of two plano-convex lenses placed in a tube with their convex sides opposite each other at a distance suited to their foci. It is intended for astronomical purposes, but is sometimes used for magnifying the image on the focussing glass of the camera. Magnifying glasses of a somewhat similar construction, but lower power are, however, generally made and used for the purpose.

Radiant, in optics, the luminous point or object from which light emanates. The *radiant point* is the point from which a pencil of light diverges, as the *focus* is the point to which it converges.

Raisin Extract.—This is a solution of grape sugar, gum, and diastase, proposed by Mr. Sebastian Davis as a preservative for dry plates. It is found in natural combination in the common raisin or dried grape. The solution is made by putting four ounces of stoned raisins into an imperial pint of boiling water, and subsequently filtering, the extract is used alone or in conjunction with albumen, in the Fothergill process, and gives fine-toned negatives.

Raspberry Syrup Process.—One of the numerous family of preservative processes, the invention of the Rev. J. Lawson Sisson. The plate being excited in the usual way, is well washed in several waters, is finally placed for a short time in a bath made of one part of the raspberry syrup sold by confectioners, to three of distilled water. It is then drained and dried. The exposure is about the same as in the Fothergill process, and the negatives very fine.

Reaction.—A term used in chemistry to describe the mutual action of chemical agents upon each other.

Recovery of Silver from Waste Solutions.—A very small portion of the silver used by photographers goes to form the picture, either on glass or paper. Not less than 90 per cent., it has been calculated, of the silver made into solutions finding its way into the sewer in various forms of waste. The simplest method of recovering the silver from the washings of prints, developing solutions, exhausted fixing solutions, and general washing waters, is to collect the whole in one large vessel, into which the sink pipe may run, and precipitate from time to time by means of liver of sulphur, as described in p. 50 of the present volume. Nitrate baths, or other silver solutions which may have become useless from any cause, may be precipitated in the form of chloride, by means of common salt. The chloride, after being thoroughly washed and dried, must be added to thrice its weight of a mixture of carbonates of potash and soda. This is placed in a Cornish crucible, and placed in a kitchen fire, the heat of which must be raised to a bright redness by means of a bellows. On allowing it to cool the silver will be found in a button at the bottom of the crucible. Various other methods of reducing silver from waste solutions have been given at different times in our columns.

Rectification.—The process of purifying alcohol and freeing it from water by repeated distillations.

Rectified Spirit.—The term rectified spirits of wine is usually applied to alcohol containing 13 or 14 per cent. of water, and having a specific gravity of about 0·835. To render this spirit absolute it is redistilled over quick-lime.

Reduction.—The process by which a metal is brought from its combinations into a metallic state. Development is a reducing process. All developing agents act in virtue of their affinity for oxygen by removing which from metallic salts, the metal is reduced into the metallic form. In all cases alkalies facilitate reduction, whilst acids generally retard the operation. The salts of iron are the most energetic reducing agents used in photography, the sulphate of iron being most energetic, and the nitrate least so. Next in energy is pyrogallic acid, and the most feeble, gallic acid. A variety of other substances have reducing properties, but are not sufficiently active to be useful in photography.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 14th August, 1861.

The flutter of excitement caused by the promised "revolutions in photography," so far from being subdued, becomes stronger every day. The prospect of being able to dispense with nitrate of silver, and of working with clean hands, is, of itself a fact calculated to inspire enthusiasm; but when coupled with the fact of complete emancipation from the snares of the abominable hypo, and the costly toning solutions, is sufficient to excite a photographic fever during these dog-days. At present, the oracles remain dumb; that they must and will speak soon, is absolutely necessary to the welfare of the photographic world. Our expectations have frequently been raised to a very high pitch, but never to the degree they have now attained. We slake our thirst as the cup of Tantalus; but if we again be deceived in our hopes, cheated in our expectations, a hard fate awaits those who have trifled with us—certainly, nothing less than having their names deeply cut on the "column of infamy." whereon are inscribed the names and offences of those who have deluded their fellow mortals.

M. Wilhorgne proposes the following method of toning and fixing positives without the use of salts of gold. He bespeaks for it simplicity of execution, great economy, and complete permanency, besides rich violet black tones and complete purity in the whites.

Five baths are, however. necessary in this method; but this must not deter the amateur from essaying a trial, as they are by no means costly. The *first* consists of a solution of hyposulphite of soda, of the strength of 20 per cent., which is saturated with chloride of sodium (common salt). This solution is always filtered before using, and a pinch of whiting is to be put into the filter. The *second* bath consists of filtered rain-water, five pints; pure carbonate of lime (whiting), one ounce. The *third* bath is composed of filtered rain-water, 100 parts; iodide of potassium, 2 parts. If filtered after each operation this bath will keep an indefinite time. But if it loses the power of yielding its primitive tones, it must be strengthened by the addition of fresh iodides, or a new bath be made. The *fourth* bath does not require to be filtered; it consists of—

Rain water	... ...	7 ounces
Hyposulphite of soda	...	45 grains
Chloride of sodium	...	15 grains
Pure sulphuric acid	...	2 to 3 drops (not more.)

The *fifth* bath is composed of rain-water 1 pint, saturated with common salt, and camphorated spirits of wine, 4 drachms. The mixture is filtered; the matter that remains on the filter must not be removed, as it serves to saturate the liquid with camphor.

The method of proceeding is as follows:—

1st. The proof in being removed from the printing-frame is immersed in bath No. 1. for 15 or 20 minutes. As in other methods, it is necessary for the proof to be somewhat over-printed, as it becomes weaker in the baths.

2nd. The proof is next rinsed, on both sides, in five or six waters, being stirred about well in each for five minutes. This operation must be very carefully performed, and must occupy not less than half an hour.

3rd. The proof is then placed in bath No. 2 for five or six minutes, then rinsed in several waters, and dried between folds of blotting-paper.

4th. When dried the proof is placed for a quarter of an hour in bath No. 3.

5th. Again dried, *without washing*, in blotting-paper, kept for this special purpose; it is then placed in the bath No. 4 immediately it assumes a milky aspect from the addition of the sulphuric acid.

Its continuance in this bath will vary more or less, according to the strength of the positive; but under the most favourable circumstances it will be from four to five minutes *at the most*. If this limit be exceeded, the strength of the solution will destroy the blacks, and make the paper tender.

As a general rule, about six or eight seconds after the blacks have visibly changed, the bath-solution must be thrown away. It can only be used once, but two or more proofs may be fixed and toned in it at the same time, the fewer, however, the better; as it costs little or nothing, a fresh bath for each operation is no object. The solution may be kept in a large stock-bottle, and when poured into a dish, the sulphuric acid be added at the moment required, taking care to agitate the solution upon the addition of the acid.

6th. After throwing the bath away, fill the dish with water, and leave the proof in it six or eight minutes. After it is well washed, leave it for half an hour in bath No. 5, then rinse it in soft water, and hang it up to dry.

All these operations should be performed out of the influence of white light.

The nitrate bath must be maintained at a strength of 25 per cent., and it is advantageous to add a few drops of nitric acid to it when prepared. If the drying of the proofs be completed before a clear fire they acquire more vigorous tones.

Evidently this is but a variation of the sulphur toning process; it remains to be seen what advantages it offers in its greater complexity.

PHOTOGRAPHY IN GERMANY.

Elberfeld, 5th August, 1861.

Dr. Schnauss, in pursuing his interesting remarks on the harmonization of photographic solutions, says:—"The amount of bromide of cadmium may be augmented in winter, in a dull light, or when operating with an old silver bath." For this purpose we prepare a strong solution o bromide of cadmium in alcohol of 9°, and add some drop of it to the ordinary iodized collodion, when necessary This is most useful when the collodion is some months old· and is red from free iodine. An excellent collodion is obtained in mixing such an old collodion with some fresh one; then it gives very clear and vigorous negatives. Reproductions of engravings, &c., are made with the old collodion alone, but then you must develop with pyrogallic acid instead of sulphate of iron, in order to obtain a white paper ground in the copy. Nothing is more difficult than to photograph a large sheet of white paper and to make a copy of this negative which is like to the original in purity and whiteness.

There is much difference of opinion respecting the effect of bromides in the collodion; some photographers think they have no effect whatever upon the sensitiveness, others believe the sensitiveness is *diminished* by this addition, and a third party think that for a good sensitive collodion an addition of bromides is indispensable.

This difference of opinion may depend upon the fact that some operators hold the obtaining of dense negatives as equivalent to greater sensitiveness; but this is an error, because the dense blacks only depend upon the development, not upon the sensitiveness of the film. Dr. Schnauss believes that film to be more sensitive which gives in the shortest time under the first, *i.e.*, the iron developer, a proof independent whether the blacks are dense or not. With a good bromo-iodized collodion the blacks are easily obtained by the following strengthening by pyrogallic acid and silver.

By adding some acetic acid to the nitrate bath the effects of the bromides are reduced, and may be quite neutralized.

When you augment the amount of iodide of ammonium and diminish the proportion of bromide of cadmium, you obtain denser blacks, but a part of the sensitiveness is lost. Prepare the four following samples:—

1. Iodide of ammonium	... ...	20 grains
Iodide of cadmium	... ...	10 ,,

dissolve in half an ounce of alcohol (90°) and add two ounces of collodion.

2. Iodide of ammonium ... ... 20 grains
Bromide of cadmium ... ... 10 „
Dissolve and add as above.

3. Iodide of cadmium ... ... 20 grains
Bromide of cadmium ... ... 10 „
Dissolve as above.

4. Iodide of ammonium ... ... 20 grains
Iodide of cadmium ... ... 5 „
Bromide of cadmium ... ... 5 „
Dissolve as above.

After eight to ten days try these collodions with a good working nitrate bath and iron developer.

No. 1 is the most insensitive one, but gives dense and clear proofs. Colour dark yellow.

No. 2 shows a too great proportion of bromide, the negatives are full of detail, but the blacks not dense enough.

No. 3 gives flat solarised proofs, and does not flow over the plate, because it contains only metallic salts. It remains colourless for many weeks.

No. 4 is the best of all, only it contains a too large proportion of bromide. After some weeks it becomes better; also when adding some drops of acetic acid to the nitrate bath it works very perfectly.

Now we come to the harmonization of the nitrate bath. In order to obtain vigorous negatives with it, I think, it should contain no free *nitric acid.* For direct positives, also for paper prints, nitric acid is indispensable. The negative bath should be prepared with alkaline, melted nitrate of silver and contain some acetic acid, in this case a small quantity of acetate of silver is formed. Then the bath is saturated with iodide of silver, exposed to daylight and filtered. After being in use a short time it will work excellently. Dr. Schnauss uses the proportion of one part of nitrate to 12 parts of water.

With a fresh bath an old yellow collodion should be used. If the proof show some fogging or want of density, add yet six to ten drops of acetic acid to the bath. No diminution of sensitiveness is remarked by this addition when working with bromo-iodised collodion and iron developer.

Dr. Schnauss believes that an iodised collodion which has been in use, *i. e.*, which has been poured off the collodionized plate, is better than a quite fresh collodion which has *never* been used.

With a freshly prepared iron solution no dense, clear, and pure negatives can be developed. The best plan is to make a four to five pounds of saturated solution of sulphate of iron, and to add some drops of sulphuric acid. Out of this bottle one fills one quarter of the operating bottle, adds three quarters of rain water, and so much acetic acid, until, after a good shaking, the fluid smells acid. A little too much acid is of no importance. The solution, when it has become yellow from the formation of acetate of iron, is in its best working state. When necessary one may also add a small quantity of alcohol, to facilitate the flowing over the plate, but with alcoholic collodion this is not necessary.

Regarding the effect of bromides in collodion, which Dr. Schnauss speaks of, I think the whole difference of opinion depends upon the kind of development. With iron developer the bromo-iodised film is more sensible than with the pyrogallic acid. The latter has not enough force, it seems to be too weak to bring the picture out as the former does. I quite agree with Mr. Hardwich's remarks upon this subject in his "Manual."

Some days ago I made a very interesting photographic tour in the beautiful vale of the Lenne, in order to photograph tunnels, bridges, and other wonders of a not yet opened railway. Arrived at the first station I found a locomotive at my disposal. I had some dry plates with me prepared after Mr. Petschler's dry process. They were immediately developed in the inner part of the tunnel, and proved to be very excellent, only the first one having had too long an exposure. I used M. Dallmeyer's Triplet Lens, No. 2, and gave an exposure of six to eight minutes.

I was induced to use the dry process mentioned by a visit of the inventor, Mr. Petschler. He had some plates prepared in England, and exposed one here in order to show me the development. The plates require more time in preparation than the Tannin plates, but nevertheless I prefer now M. Petschler's plates. With alcoholic collodion they seem also to be more sensitive than the Tannin plates, and the film is more perfectly attached to the glass plate.

Paul E. Liesegang.

HARMONIZATION OF CHEMICALS.

Sir,—Having lately amused myself by trying the dry gum process of Mr. Sisson, and finding the disposition to fog mentioned by yourself, it struck me that as there can be no effect without cause, I would endeavour, as far as my knowledge would permit, to ascertain the cause.

On testing my chemicals, I found the collodion possessed an *acid* reaction; the sensitizing bath; *ditto*, the gum solution, slightly *alkaline.* here it struck me, reasoning from analogy, that I had found the true cause of the difficulty. I will tell you, Mr. Editor, why I come to this conclusion, as I believe it will be found a common cause of failure in *all* processes.

If we proceed to take pictures by wet collodion simply, we have lately a high authority for asserting that the collodion *must* be *acid*; the sensitizing bath to work with any certainty must also possess a slightly acid reaction; the developers, we know, must contain acid: here we have a certain amount of uniformity throughout the process. Again, let us take a printing process, the ammonio-nitrate; the best papers are foreign ones, possessing an alkaline reaction, most operators in this process prefer ammonium for the salting solution; the gold bath should be at least neutral, if not slightly alkaline; fixing bath, ditto: here again we see the necessity of a similar amount of uniformity to ensure success. With the albumen papers the same necessity for neutrality or slight alkalinity throughout may be traced; many of the failures with the new gold bath, no doubt, arising from acidity in the papers or in the sensitizing bath. Some operators advocating the use of acids in these preparations.

Again, let us return to the wet process for negatives; if we take a plate, coat it with collodion (usually having an acid reaction), dip it in a *neutral* silver bath, develop with the ordinary developer (that is, without an extra addition of acid), and see if the negative does not have the fog, that makes it so difficult to use a neutral bath with any satisfactory result; it is no answer to tell me that many operators do use a neutral bath successfully with the other chemicals in their ordinary condition. I ask how do they know the bath to be neutral? surely, not by the litmus paper test? I have no faith in their ability; the test very delicate reactions by such means, and I believe that if we possessed a more delicate test for acidity or alkalidity we should find that what they consider to be neutral would really prove to have a slightly acid reaction but requiring a more delicate test than any we at present possess. May we also trace the beneficial action of gallic acid on dry plates to the fact of its restoring the balance previously displaced by the alkaline preservatives, such as albumen, &c.? I merely give this as a possible solution.

Another word, sir, regarding the test papers. I think any one who has had experience, and observed accurately, will agree with me that litmus and turmeric papers are very coarse tests for chemical reactions. I do not consider myself a chemist, although I am partial to the study; but I assert that test papers will merely show that a solution is *decidedly* acid or alkaline, and that they are almost useless where exceedingly delicate reactions are necessary. I do not know, sir, if you will consider these observations worth a place in your valuable journal; but I firmly believe, that I have indicated so common a cause of failure, that it should be impressed on the mind of every photographer or scientific man, that, in giving the public any description of success or failure, whilst giving the minute details, he should also take a broad view of the necessity of harmony or unity in every part of his process.—I am, sir, yours respectfully, E. E. L.

[It is quite possible that the suggestion of our correspondent regarding the cause of the occasional tendency to fogging in the Rev. J. Lawson Sisson's process may be correct, and that a more acid bath, a more acid collodion, or the addition of a trace of citric acid to the preservative might prove a remedy. We think he overlooks the fact, however, that it is a proper balance, or harmony, which is required in the chemicals; not uniformity of condition. If the collodion be neutral, the bath must be acid; the more nearly neutral the bath, the more decidedly acid should be bath or developer. In printing, the silver bath gives best results when decidedly acid, although the paper inclines to alkalinity, and the toning and fixing must be alkaline or neutral.—Ed.]

STEREO EXCHANGE CLUB.

Sir,—I, like your correspondent "Stereo," am one of the discontented members of the Stereo Exchange Club, and, like him, long for an alteration in the rules and method of working. Some of his ideas are certainly very suggestive; and I have ventured to trouble you with my own views on the subject, so that we may, if possible, make a fresh start.

I would begin by suggesting that a secretary be appointed by you from the names of those gentlemen who will volunteer their services for twelve months.

That each gentleman desirous of joining the club send in his name to the secretary, accompanied with twelve postage stamps for twelve months.

That during the first week of every month members desirous of exchanging prints forward to the secretary not less than three or more than six good prints.

That during the last week in every month the secretary shall forward to such members the same number of prints of similar quality and subject as those received.

That in the event of any member's prints not being equivalent in value, photographically or otherwise, with those received from other members, they be returned to him with an intimation to that effect.

The result would be that, if a member pleased, he could make six dozen exchanges each year, or less if it so pleased him; the surplus pence to pay for envelopes, &c.

All that would be required from the secretary would be strict impartiality in making the exchanges, and in selecting and rejecting prints.

These exchanges to be made quite irrespective of any that may have been made previously between gentlemen of the club; and any member, wishing to avoid receiving duplicate prints, to forward a list to the secretary of what he already possesses.—I am, sir, yours respectfully,

A Volunteer Secretary.

August 12, 1861.

[We shall be glad to hear further opinions on this subject. The propositions appear most sensible and desirable.—Ed.]

Photographic Notes and Queries.

India-Rubber for Baths.

Sir,—I was much surprised on looking over the News of to day, to find that the invention of india-rubber baths is attributed to Mr. Francis. If you will refer to your number for the 15th of February, 1861, you will there find my full description of the mode of making india-rubber baths, and also a suggestion for a wooden bath, lined with india-rubber. In my description you will find that I have made a remark to the same effect as yours of to-day, namely, that "pure india-rubber is without action on the solution of nitrate of silver, and may be used safely." Hoping you will find a corner for this, I am, sir, truly yours, Leo Daft.

2, *Queen Square, Westminster, August 9th*, 1861.

[We are at all times unwilling to rob any member of the photographic commonwealth of the credit of any suggestion he may have contributed to the public stock, as that credit is the only reward for so much that is freely imparted. In noticing Mr. Francis' baths, we did not give him credit for the first use of india-rubber for baths; but for having made a very simple and efficient application of it as a lining to wood. Our readers will remember the valuable letter of our correspondent on the subject some months ago.—Ed.]

Miscellaneous.

Photographic Micrometers.—Dr. Wood, writing to the *Philosophical Magazine*, referring to the subject of photographic micrometers, regarding which a paragraph, copied from one of our American contemporaries, appeared in our pages a few weeks ago, stating that photographic micrometers had recently been constructed by Mr. C. Morfit, of New York, remarks:—"I have been for the last month, or so, engaged occasionally in making experiments with the same intention as an original idea. I send you a short account of what I have done for publication, if you think it sufficiently interesting.

"My endeavour was to get a glass slide for a microscope, marked so as to measure very minute objects; and as the micrometer I have (measuring 1-100th of an inch) was useless for the purpose I had in view, it occurred to me that by the diminishing power of the camera I might succeed in obtaining smaller divisions. I tried first for pictures of dark lines, 1-16th of an inch in breadth, on a white ground, reduced to a small compass, but I did not succeed, even with a very small aperture to the lens. I then substituted lines 1-4th of an inch in breadth removed to a greater distance, and I got a pretty sharp picture; but I found that the sharpest and best-marked picture of distant lines I obtained was given by opaque bars, placed so that the light from a clear sky came to the camera between them.

"By nailing rods of blackened wood, 1-4th of an inch broad, and 1-4th of an inch asunder, across a frame, and placing this at a suitable distance, with a clear light behind, and using an aperture of about 1-8th of an inch in diameter, I easily obtained well-marked and sharp lines, the 1-1000th of an inch apart, and the 1-1000th of an inch in breadth, sufficiently accurate for all the purposes of a micrometer. The picture of the lines requires to be covered with transparent varnish to prevent rubbing. I have taken the picture on very thin talc, and cemented it to glass, with the collodion between the plates; and for object-glasses of small power I have found it answer, but the thickness of the talc is too much for the higher powers, as the object viewed and the lines do not sufficiently agree in focus.

"I suppose the reason why lines, with spaces between them, give a better picture than black lines ruled on a white ground is, because there is no irradiation of light from behind, at least not nearly so much from the spaces as from the white ground. At all events, whatever the cause may be, I have found the lines with the spaces give a much better and sharper impression. The picture of the lines should be a positive one, and very clear. I found the collodion prepared with the iodide of iron, according to the formula given in this *Magazine*, July, 1854, to act admirably. It must be very sensitive, on account of the smallness of the aperture necessary for the required sharpness. I have no doubt that much finer lines than these I have got might be obtained by the same process."

Gun Cotton.—Gun cotton is a material for which we have no satisfactory test but the actual trial. We cannot tell if it will dissolve or no till we try it, we cannot tell if its solution is fit till we use it.

One of the strangest facts about pyroxyline is, that it is utterly insoluble in ether or alcohol separately, while if the ether and alcohol be mixed, it melts away in solution rapidly. This fact is anomalous, and, as far as I know, has not a parallel.

How admirable is the mixture which we call collodion, for our photographic process. I believe if the wisest man had been required to name the properties of the great desideratum, he would have given the description which could apply to nothing but collodion. He would have said, let a fibre-like cotton, insoluble in water, be dissolved in a liquid which dissolves also iodide of potassium. The solvent must be volatile, and must be unaffected by nitrate of silver. Twenty years ago such a combination was as far beyond reach as the *elixir vitæ*. The problem is now fairly and practically solved, but it is only the expert that are able to make the happy combination in all its perfection.

There are lately found other solvents than ether-alcohol of gun cotton, namely, aniline and nitro-benzoin. And I think it likely that pyroxyline will dissolve in all of the nitro-hydrocarbons. Here is a promising and unexplored field for research. Perhaps we shall discover a new collodion! Let some one try to resolve the scientific mystery of gun cotton.—*American Journal of Photography.*

Talk in the Studio.

The Tannin Process.—Mr. Russell's long-promised treatise on the tannin process is out, and has just reached our hands. Instead of a mere tract, as some may suppose, it is a respectable volume of 80 pages, entering very fully into every point of minutiæ. We shall devote more space to an account of it in our next.

Plate Holder for Developing.—We have received from Mr. Solomon a plate holder he has just brought out, for holding the plate during development. We have seen and tried a variety of contrivances for this purpose, but the one before us entirely eclipses in simplicity and efficiency any we have before met with. It consists of a shank of stout silver-plated wire, at one end of which is a ring which forms the handle; and at the other, a fixed gutta-percha rest or shoulder. Opposite to this is another shoulder of gutta-percha, which slides along the wire. Stretched over the fixed and the moveable shoulder is a vulcanized india-rubber band. In each piece of gutta-percha is an aperture, so that when a plate is placed with one corner in each gutta-percha rest diagonally, it only touches at the extreme edges. The plate is held firmly in this position by the india-rubber band, which by its elasticity holds with equal facility any size, from a quarter-plate to a whole-plate, or larger. The contrivance is light, compact, efficient, and cheap, and will completely realize the possibility of photography with clean fingers.

The Photographic Nuisance.—The public have been generous patrons of the photographer. The photographer, in his turn, has done much towards the education and refinement of the people. But we hardly care to pass our lives before the truest camera. We cannot consent to be sitting for our portraits from sunrise till sundown. We protest, therefore, against a street nuisance, born of photography. It offends us at every turn; it dodges us at every corner. Ruthless fellows of savage exterior, thrust black portraits under our nose in every street, and have, now and then, a sneer or an impertinence for the passer-by who declines to follow them up to the glass-house, where "the artist" officiates. We have been compelled to touch upon this subject by the outrage a woman has recently suffered at the hands of some of these importunate photographers, because, forsooth, she ventured "to hint a fault and hesitate dislike" when she was supplied with her portrait. People will hesitate to risk the taking of even the cheapest portrait, if the bargain is likely to include a black eye.

There is a story told of a tradesman who vowed that he could not be civil to everybody. But we shall presently have a set of portrait-hawkers who will find it difficult to be civil to anybody. —*Lloyd's Weekly News.*

To Correspondents.

Toning.—We have generally succeeded perfectly with every formula of gold toning we have tried, using, in conjunction with the gold, phosphate, carbonate, acetate, and citrate of soda, and also Legray's formula with chloride of lime. The mottled, mealy, grey effect in the print you forward, is very troublesome; we have at times met with it, and have often heard of it. The cause is difficult to determine certainly. It is more common with some samples of paper than others, but it is not always necessarily the fault of the paper. When we have met with it we have been somewhat disposed to attribute it to the washing water before toning containing carbonates, which precipitated a carbonate of silver in fine patches, some of which adhered very firmly to the surface in this mottled manner, preventing toning in these parts, whilst other points were being over-toned. But we have not met with it sufficiently often to say that this is the reason; nor do the best remedies we know confirm this view. Amongst the skilled practical operators we know, there are several who have entirely got over this difficulty by using acetate of soda in the gold bath. The proportions stand thus: chloride of gold, 15 grains; acetate of soda, 7½ drachms; water, 35 ounces. See also Mr. Elliot's recent paper in our pages, "The Measles: its Diagnosis and Cure."

B. K.—A report on your glass in our next.

J. J. A Constant Reader of the News.—A positive which has just received the proper exposure, and no more, will not make a very good negative. However, proceed as follows: make a solution of two grains of iodide of potassium and one grain of iodine in an ounce of water. Wet the film of the picture to be strengthened, thoroughly, and then cover it with this solution and leave it on for a few minutes in the light. Now wash again thoroughly, and develop in the dark room, with pyrogallic acid 2 grains, citric acid 1 grain, in one ounce of water, adding to this developer a few drops of 20-grain solution of silver. When sufficient intensity has been gained, wash and dry. Or, instead of this method, after wetting the film, pour on a solution of bichloride of mercury three or four grains to the ounce, leave it for about a minute, wash well, and then pour on a solution of iodide of potassium one grain to the ounce, which will turn the picture a greenish yellow, then wash well, dry and varnish. Whichever plan you adopt try it on a waste plate or two first, to make yourself familiar with the reactions before you risk it on a picture you value.

Thos. Llewellyn.—Dallmeyer's triple achromatic lens consists of two achromatic meniscus lenses of different diameters and foci, with a double concave achromatic lens between them. The form of your half-plate lens is that usually adopted for portrait lenses. The terms "actinic focus," and "chemical focus" have the same meaning, and they are distinguished from the "optical focus" by the fact that in lenses not corrected so as to have their optical and actinic foci coincident, the actinic rays of light do not come to a focus at the same point as the illuminating rays, and the focus as seen, is not that at which there is chemical action. If these answers do not clear up your difficulty, write again, but to answer you fully would really require an elementary treatise on optics. Dicks' "Practical Astronomer," if our memory serve us correctly, was about 7s. We believe it is out of print.

A. A.—We have not met with such markings before. They appear from their form to arise from turbidity of some of the solutions which have been poured on the plate, but whether in the preparation of the plate, or its development, it is difficult to say. We have seen somewhat similar markings, but not so numerous or quite of the same form, on developing a dry plate, from the vessel holding the solution not being quite clean, causing the developer to become quickly turbid on adding the silver, which become deposited in irregular spots on pouring it on the plate. The general character of the negative is faulty, and seems to indicate alkalinity somewhere.

F. J.—The oily appearance of the plate in the nitrate bath may proceed from two causes, or a combination of both. If the bath be an old one it arises from an accumulation of ether and alcohol in it, and may be got rid of by placing the solution in an open vessel in a warm place, to evaporate part of the excess of ether and alcohol. It more probably proceeds from the collodion, the pyroxyline having been made at a low temperature, and giving a film which is horny and repellant of water, or containing much anhydrous spirit. In this case a drop or two of distilled water to each ounce of collodion will probably cure the evil. 2. The loss of tone on placing the print in the hypo bath often arises from faulty paper, and indicates weakness in the salting solution with which it was prepared. The only plan is to change the paper, or in using the same, tone a little deeper. A freshly made hypo solution is most apt to produce the effect. It will not be so bad after a few prints have been fixed and partially satisfied the propensity the hypo possesses of attacking the gold. Take care, however, that your hypo does not become acid, and also not to continue its use until it is quite exhausted. See Mr. Eliot's two recent communications on this subject.

T. Y. K.—You are giving excessive over-exposure. In copying prints it is generally a question of seconds rather than minutes unless you are using a very old collodion and very small stop in the lens. The collodion you are using is not well suited to the work; you should have an old intense collodion of the colour of brown sherry. If you then do not get sufficient density, you can further intensify with bichloride of mercury. A negative of an engraving should generally have a few points to represent white paper, quite black and opaque, and the deep shadows almost bare glass.

M. H.—It is difficult to state absolutely the comparative value of different lenses without careful comparative trial. As regards the question of straightness of marginal lines, however, there cannot be a moment's doubt of the superiority of the triple over those you name, or indeed over any other landscape lens, and we think its advantages are as marked in the 6 by 5 lens as in any other size. We use one of that size, and regard the definition as most perfect throughout, and its action decidedly rapid. We should decidedly prefer it to those you name; but how far it is worth while, possessing those, to procure this, must be a question for individual judgment.

Five Months.—1. The deep shadows under the eyes in your portraits, taken in the open air, arises from the excess of vertical illumination. The light comes direct upon the head, and the forehead and eye-brows cast shadows underneath the eyes. Erect some kind of canopy, so that the sitter is protected from the direct top light. 2. Portraits cannot be taken by gas light. 3. The defect you name is, we believe, incident to the process. Try the Fothergill process.

James Tulley.—We think we have seen the picture you name, but as we have not access to a copy for examination, and do not remember it accurately, we cannot speak definitely about the matter. You must remember, however, that a photographer may be highly skilled in the studio; but quite at a loss in work out-of-doors. We do not regard the firm you mention, as producing first-class work.

J. C.—We do not quite understand the kind of markings to which you refer. An excess of water in your collodion may produce markings in two ways; either by causing craping and reticulation, or by making it so gelatinous that it gives an uneven layer full of small inequalities or lumps. The former you may remedy somewhat by allowing the film to set well before immersion in the nitrate bath. If it be from the lumpy inequality, the addition of a little more ether will mend the matter. The use of a more powdery pyroxyline will of course prevent gelatinization and uneven film; age, and the use of an alkaline iodide, will have a similar effect. Mr. Davis uses the raisin extract in connection with albumen. We have tried it and found it excellent. We think it better for the purposes than the sugar syrup: if the latter be used it should be considerably more diluted. 2. The best book for reference is Hardwich's Manual.

H. Cooper, Jun.—We will write to you.

F. S. Beatty.—We will write to you in a few days.

H. R. Nichols.—We shall look with interest for the results of your experiments when they are brought to a successful termination.

R. J. P.—It is very difficult to succeed in albumenizing paper without producing streaks. It requires much experience and skill in manipulating to succeed always, and some papers are more difficult to manage than others. The difficulty is of course much increased, if you use pure albumen without dilution with water. What is required is greater limpidity. The addition of acetic acid certainly increases the limpidity; but whether it will in all cases prevent streaks or not, we cannot say. We cannot give you any other information as to the means of avoiding these streaks than that which we have before published.

M. D.—The objections to using a 12 by 10 lens with a 7½ by 5 camera, are, in the first place, that the focus of the larger lens would be double the length of the small one, and the body of the camera could not, with any convenience, be made to draw out so far. The proportion of the objects and the amount of subject included by a large lens, on a small plate, would often be clumsy. 2 A single view lens may be used for copying, but the field is not flat, the lines are curved, and the definition is often imperfect. The triple lens is best for copying.

T. P. E.—In our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 155.—*August* 23, 1861.

ROYAL PATRONAGE OF PHOTOGRAPHY.

Every photographer is aware that both Her Majesty the Queen and the Prince Consort have at all times exhibited a lively interest in photography, and that the Photographic Society of London is under their direct patronage. It has even been whispered that the royal fingers have not unfrequently been impressed with the universal insignia of the votaries of the art, the inevitable black tips. However that may be, it is a highly gratifying circumstance to record, in connection with Her Majesty's patronage of the art, that it is always marked by a most discriminating appreciation of excellence, and that the men photographers generally are proud to own, are the men Her Majesty delights to honour.

In London it is from amongst photographers admitted by the universal consent of their *confréres* as in the first rank, that selection has been made. Such men as Williams, and Kilburn, and Lake Price, and Mayall, and Southwell have been summoned at different times to the Palace, and in some instances have been permitted to publish the results of their labours for the gratification of the community at large. At Balmoral the nearest resident photographer of ability—one recognized unhesitatingly by photographers as amongst their best men—Mr George Wilson of Aberdeen, has repeatedly been commissioned by Her Majesty. Now we have to record that Mr. Lacy of Ryde, to whose exquisite pictures we have more than once called attention, has been summoned to Osborne to produce *carte de visite* portraits of various members of the Royal Family.

We cannot but regard the publication of these photographic portraits as a happy thought on the part of Her Majesty, and as at once calculated to stimulate and gratify the proverbial loyalty of the people of England, whilst it evinces on her part that desire for a place in the hearts and memories of her people, which Shakespeare renders as so finely characterizing a monarch centuries ago, who enthusiastically exclaims—

> "Then shall our names,
> Familiar in their mouths as household words,
> * * * be freshly remembered."

In a recent visit to the Isle of Wight we had the pleasure of inspecting the negatives and early proofs of the pictures taken by Mr. Lacy at Osborne. Amongst these were portraits of the Crown Prince Frederick William of Prussia, and the Crown Princess (Princess Royal of England), and their two children, the Prince William and Princess Charlotte, and also the Princess Beatrice, together with several ladies and gentlemen of her Majesty's and the Crown Princess's suite. The portrait of the Crown Princess in a group with her husband the Prince Frederick William, is by far the happiest we have seen. The group itself is an elegant little composition, but the portrait of the Princess is so simple and graceful in *posé*, so sweet and winning in expression, that we have rarely seen a more charming picture, or one which does so much justice to its original. After this, by far the most attractive picture is the portrait of the young Prince William of Prussia, a handsome boy of two years and a half old, in the traditional costume of a true British tar, and looking every inch the character. Had this been the portrait of some infant dramatic prodigy enacting the various characters of T. P. Cooke with great success, we should have regarded it as a miracle of clever acting. The loose shirt and large collar turned over a cravat, which is slung rather than tied round the neck, the loose trousers, tight above and flowing below, and sailors' hat stuck on the back of the head, complete the costume. The figure is poised on one leg, whilst the other foot rests on its side, giving a slightly heeling effect. The hands are in the trouser pockets, one being thrust deeply down as if in search of the last stray sixpence; the position of the head and general expression lending countenance to that idea, and giving an irresitible piquancy to the whole picture. These, with several other interesting portraits, Mr. Lacy has received Her Majesty's permission to publish, and they will shortly be ready for distribution.

Mr. Mayall has also just announced that his recent series of the Royal Family are now ready for publication. We had the privilege, some months ago, of seeing the early impressions which had just been submitted to Her Majesty's inspection. They far exceed in interest and variety the first series issued by Mr. Mayall; the costumes, and the expressions, both being more pleasing than those in the former series. They consist of single and grouped portraits of Her Majesty and the Prince Consort, in various positions, portraits of the Crown Princess, and the Crown Prince of Prussia, of the Princesses Alice, Helena, and Beatrice; and of the Princes Louis, Arthur, and Leopold. The series is of considerable extent, and embraces some very fine specimens of photographic portraiture.

We cannot help here, in reference to the pictures we have mentioned, expressing our deep regret that the Bill for amending the law of copyright as relating to works of fine art, did not pass into an Act during the last session of Parliament. Read a second time, and committed, it was placed in the orders of the day repeatedly, and as repeatedly from some cause or other delayed, until the end of the session came, and it shared the inglorious death known in the slang of the house as the "slaughter of the innocents." The specific protection there provided for photographs, is at least delayed for a great part of twelve months longer.

Mr. Mayall and Mr. Lacy will issue these portraits with a full conviction that they will be pirated. The wrong thus done to their purses is the least part of the evil. The coarse, granular, flat, stained, fading copies which will appear—for the pirate is genarally a bungler—will in many cases be mistaken for their work, and their reputation will suffer; the art will be degraded, and the illustrious person portrayed will be caricatured. We cannot but think that the present law might be administered so as to be a protection in palpable cases; but as the cost of a trial must be heavy, the question arises "who is to bell the cat?" We believe an attempt was recently made to form a combination for such a purpose; but failed through a disposition on the part of those concerned, to thrust the chief onus on one person, who was naturally indisposed to try, at his own cost, a question in which all publishers of photographs are interested. For the present we fear that there is nothing to prevent this disgraceful piracy, but the refusal of all dealers to assist in the distribution of the stolen property.

PHOTOGRAPHY AND THE INTERNATIONAL EXHIBITION.

The correspondence between the Council of the Photographic Society and Her Majesty's Commissioners for the Exhibition of 1862, has for the present terminated; and, we regret to say, unsatisfactorily. The Commissioners have not distinctly denied the claim made by the Society for a position amongst the Fine Arts, but have, in a manner we must confess the Council have a right to regard as somewhat rude, quietly ignored the claim. Our readers are aware that in the last letter of the Chief Baron to the Commissioners he suggested that they should receive a deputation from the Society in order that the question might be fully considered. The Commissioners declined to receive a deputation, but expressed their anxiety to have a committee appointed to co-operate with them in the matter. This was deemed unsatisfactory, and on June 11th, Dr. Diamond wrote to the Commissioners informing them that the Council could not take any further step until they had ascertained the views of photographers generally on the subject. No further communication appears to have passed between the Society and the Commissioners until the end of July, when the following letters, which we find in the society's journal, were forwarded :—

Offices, 454, *West Strand, London, W. C., July* 29, 1861.

Sir,—Adverting to your letter of the 12th of June, I am directed by Her Majesty's Commissioners to inquire whether the Council of the Photographic Society are yet able to favour them with a definite reply as to the nomination of a Committee in connexion with Class 14. The Commissioners will be glad if the matter could be settled in the course of the current week, in order that they may conclude their arrangements in connexion with this department of the Exhibition.—I have the honour to be, sir, your obedient servant,

F. R. Sandford, *Secretary*.

To Hugh W. Diamond, Esq., M.D.

To this Dr. Diamond replied that nothing could be done until they had conferred with the Chief Baron, who was then absent on circuit. In a few days after the following letter was forwarded to the Commissioners :—

Photographic Society, August 8, 1861.

Sir,—The Council have no wish to dictate to the Commissioners in what form their just expectations shall be fulfilled. If the Commissioners are prepared to receive Photography as a branch of the Fine Arts, the Council are willing to appoint a Committee, and afford every assistance in their power.

But if this be not conceded, the Council cannot concur in any proceeding, the tendency of which is to disparage Photography as one of the now universally acknowledged means by which genius can perpetuate whatever is grand and beautiful in Nature.—I am, sir, your obedient servant,

Hugh W. Diamond, M.D., *Secretary*.

To F. R. Sandford, Esq.

To this, so far as we are aware, no answer has been received ; and, if we understand the matter rightly, there is an end of any hope of co-operation on the part of the Photographic Society in the arrangements of the Exhibition. " Nothing now remains," observes the editor of the Society's journal, " but to allow matters to take the natural course." What is meant by the " natural course " is not stated ; but as abstaining from contributions to the exhibition was the course before recommended in case the Commissioners declined to comply with the claims made for photography, we presume that is intended here. The suggestion is added that if photographers generally approve of the idea of holding an independent contemporaneous exhibition for photographs, promp action is requisite.

We must confess that we feel very loath to regard the matter as definitely settled thus. We shall deeply regret if photography have no representative of its interests in the arrangements of the International Exhibition. An independent exhibition we regard as a poor substitute for an honourable position in this great international undertaking; and as it is quite certain that photographers will contribute to the latter, the existence of an independent exhibition will only tend to spoil both and prevent either having a representative character. The Council of the Photographic Society have doubtless endeavoured to maintain the dignity of the art in this matter, and deserve the thanks of photographers for the attitude they have preserved throughout this matter ; but we cannot help regretting that a Committee was not appointed, who might possibly have secured, in the progress of arrangments, many advantages which will otherwise be lost. Possibly, effect might have been given to the suggestion of Mr. Sebastian Davis made at the last South London meeting, and advocated at the time by ourselves—which by the way we have been somewhat amused to see revived in a recent number of a contemporary as an original suggestion—in which he proposed that art-photography and general-photography, might each have a distinct recognition and position. An arrangement like this might, possibly, more easily have been brought about than the admission of photography generally into the fine art section.

M. Claudet, in an able letter to the Society's Journal, in which he fully endorses the position assumed by the Council and admits many of the advantages obtained by an independent exhibition, comes to the conclusion that, after all, submission to the classification of the commissioners will be the best course. He observes, that although doubtless sufficient unanimity amongst English photographers might be secured to render a separate exhibition a success yet,

" The difficulty of having the adhesion of foreign photographers from all parts of the world, ignorant of the real state of the question and of the classification decided by the Royal Commission, will perhaps leave us no other alternative than to submit to the classification, which, however unpleasant to the scrupulous and spirited photographer, cannot affect the ultimate object of the presence of photography in the palace of the Great Exhibition, which is to enable the public to judge of the present state of the art, and to compare the progress made by every nation in that most beautiful discovery, whether it is classified in the catalogue under the head of machines or fine arts.

" I hope that such an act of humility, and such a sacrifice from our part as individuals, will be understood, and that we shall come out of the International Exhibition with the greatest honour, having conquered once for all, the rank, in the acknowledged fine arts, which belongs to photography.

For the present it appears we must wait the course of events. In any case photographers have something to learn from the matter. Her Majesty's Commissioners have decided that photography is a mechanical art, and that photographs are mechanical productions. Have photographers nothing to charge themselves with in this matter ? That photography is a fine art we think there can be no room for rational doubt. But how many photographers are artists ? How many are there who know anything of the principles of art in their most rudimental forms ? Photography is undoubtedly a fine art ; but how many photographs are works of fine art ? Painting is a fine art ; but it is only so in the hands of an artist. So little attention has been given to art-culture amongst photographers, that almost the whole terminology of the art is of a mechaneal character. Is a picture very fine, the question at once asked is, " by what *process* was it produced, and with what lens ?" When a process is described, it is the *manipulations* which concentrate the interest ; and the person who practises photography professionally is an *operator*.

Amongst photographers themselves, the mechanical appliances have been often exalted over the artistic conception, and some of our most artistic photographers have pined for lack of appreciation. Let us look to it then, and whilst we maintain the art-claims of photography, endeavour to improve the art-character of its productions

FORMIC ACID IN THE DEVELOPER.

In a letter we have just received from the Hon. Major Stuart Wortley, now in Naples, he gives some details of his experience as to the effects of formic acid in the developer, which will be interesting to our readers. We may remark in passing that Major Wortley is an enthusiastic and skilful photographer, and that the very finest negatives we have seen of Indian scenery were produced by him. His opinion is, therefore, of weight, as coming from a cultivated and experienced amateur. He says :—

" Having been interested in reading the controversy regarding the employment of formic acid in the collodion process, I will give you the result of my experience with it. Working in India two years ago, I was first induced to employ formic acid in consequence of its great restraining tendency; I found it to allow the iron developer to be poured on to the film as the hottest weather without difficulty, while at the same time I found that I could obtain an equal amount of half-tone and intensity in my negative with less exposure than when using acetic acid alone.

"I am convinced formic acid is injurious in the bath, and is only of use in the developer. Since that I have, within the last two months, had an opportunity of verifying my previous experiments. I have made a careful series of experiments, and find the following the most satisfactory proportions that I have yet hit upon:—

Water	18 ounces
Sulphate of iron	200 grains
Formic acid	3 drachms
Acetic acid	4 ,,

I enclose you a print vignetted from one of my negatives, in order to give you an idea of the results; and I may mention that the negative after development with iron, is washed, cyanide applied, and then dried. I afterwards intensify, and I think you will agree with me that it is not often easy, by intensifying, to obtain such perfect gradation of tone, and, in this instance, with a very difficult subject. The statue is a copy from the famous Venus Kalipyge in the museum here, and stands, as you see, in the garden of the villa in which I am staying."

The vignetted print enclosed to us is a most exquisite picture, and equal as a photograph to anything we have seen, notwithstanding that it is, as Major Wortley remarks, a very trying subject. The white statue stands against a white background, and is surrounded by green foliage; notwithstanding which, there is the most perfect rendering of every delicate gradation in each. The statue is no flat patch, but perfectly round and relieved, giving every gradation of the modelling; every leaf is at the same time perfect and full of half-tone. The texture of the bark of a tree is quite microscopic in its exquisite definition and detail. We have rarely seen a photograph more perfect in all its parts.

Formic acid has been repeatedly suggested and tried as a photographic agent, but generally, for some reason, abandoned. It has been repeatedly recommended as an addition to the iron developer for glass positives as materially improving their tone. We used it for this purpose, experimentally, some years ago; but gave it up as tending to fog the shadows. It, unquestionably, has some reducing power, and hence we should not, *a priori*, have anticipated that it would have been valuable in restraining development. But one well ascertained fact, one successful result, is worth many speculations. That it should be added to the developer and not to the bath, there should never have been a doubt. If added to the latter, especially if it contain no other acid, fogging must result, with eventual precipitation of formiate of silver.

A FEW HINTS ON INSTANTANEOUS PHOTOGRAPHY.

There are few things more interesting to a young amateur, who has devoured with avidity several Instruction Books, than to know the actual details of manipulation, by which some specific successes of a kind in which he is interested have been produced. We have repeatedly stated that for the practice of instantaneous photography, the requisites were simply the ordinary chemicals and appliances of the best kind, and in the best conditions: a good bromo-iodized collodion; bath of pure silver, with no more acid than is necessary for clean working; iron developer, good lenses, and good light. But still we are asked from time to time for more particulars as to the production of such and such instantaneous pictures.

Mr. Harman has favoured us with a brief statement of the method used in producing the instantaneous views of London, recently noticed in our columns.

We subjoin his communication:—

"One of the first things to be considered in the production of instantaneous photographs, is to have a contrivance for opening and shutting the lens quick enough to obtain sharp pictures of moving objects. This may be managed in a variety of ways, and each photographer will probably select his own method. But by far the most difficult point to overcome is to have a process by which you can get fully detailed exposed negatives with such rapidity of exposure. The following process is always successful in my hands.

Plain Collodion.

Take—Ether ·750	8 oz.
Alcohol ·820	1 ,,

add good pyroxyline until thick enough.

Iodizer.

Take—Alcohol ·820	3 oz.
Iodide of Cadmium	54 grains.
Bromide Ammonium	18 ,,

When the plain collodion is sufficiently settled add to every 3 ounces 1 ounce of iodizing solution, shake well, and set aside for four or five days to settle, when the collodion will be ready for use.

The Bath.

"Dissolve 1 oz. of nitrate of silver in 2 oz. of distilled water, and 4 grains of iodide of potassium in about 1 drachm of distilled water. Mix, and when the precipitate is dissolved add 12 oz. more distilled water. Shake well, then add a small quantity of moist oxide of silver, until it assumes a dirty brown colour; shake again very well, and filter (sometimes it requires twice filtering to make it quite clear), then add 2 or 3 drops of diluted nitric acid until the solution give a faint acid reaction to test paper, when it is fit for use.

Developing Solution.

Water	6 oz.
Protosulphate of iron	2 drachms.
Glacial Acetic Acid	3 ,,
Alcohol	2 ,,

"Great care must be taken to have perfectly clean glass plates. When these are obtained, coat with collodion, sensitize, develop until all the detail is well out, fix (with cyanide), and wash in the usual way. When the negatives are dry, pass a camel-hair brush, dipped in spirit varnish, round the edge. When this is dry, moisten the film with water, and re-develop with strong pyrogallic solution to which a few drops of silver have been added. If sufficient intensity cannot be obtained with this, wash the plate well and pour over a weak solution of bichloride of mercury. This seldom fails to bring it up to the desired point. But sometimes it is requisite to wash again, and treat it with a weak solution of iodide of potassium. When the negative is finished, wash well and dry. Always avoid using the mercury too strong, as it often happens that it renders the negative white instead of blackening it. In conclusion, I will mention that the lenses I use were made by Dallmeyer, and in my humble opinion none better can be obtained for the purpose. Alfred Harman.

3, *Albert Cottages, Hill Street, Peckham, S. E.*

THE TANNIN PROCESS.*

Major Russell has left no opening for the dry photographer to complain of scanty information regarding the Tannin process.

Our readers have already had very clear and very lucid articles from his pen describing the process; now we have before us a work on the subject, perhaps the most complete, minutely detailed, and comprehensive treatise which has ever appeared on any single process in photography. We have rarely met with a photographer having such a method-

* "The Tannin Process," by C. Russell.—London: John W. Davies; and Liverpool, H. Greenwood.

ical and systematic plan of proceeding from the beginning to the end of all his operations, together with such simplicity and clearness in explaining them and presenting the reasons for each. The work itself partakes of the character of the science, and is pre-eminently photographic in its perfect rendering of minutiæ. We have not less than a dozen pages under the heading "Coating with Gelatine," and nearly as many more under "Coating with Tannin." This is just what a very large class of readers require. Starting as in many instances they do, without previous knowledge of, or practice in the manipulations of dry photography, they require a routine so clearly defined that they cannot err if they follow it, together with such an intelligent explanation of the reasons as removes them from the position of mere automatons in the pursuit of their art. Major Russell does not believe in hap-hazard methods of proceeding; but recognizes a right and wrong method of performing the simplest operations: the right he points out and enforces, the wrong he points out to be avoided; and he has a always sufficient reason for his election in matters so trivial that many photographers would fail to observe, still less make notes upon.

The simplicity and certainty of the process, with the excellence of the results when carefully managed, will render this little work welcome to many. In all the main points the details are just the same as those communicated by Major Russell in our columns some months ago, the present treatise being an elaboration rather than a modification of what was before published. We shall, however, for the benefit of those interested in the matter, make a hasty *resumé* of the process as now published, which we hope will tempt our readers to procure and peruse the work itself.

To commence with cleaning the glasses—which for this process, it is stated, should, unless gelatine be used, always be ground at the edges and a little way on to the surface—Major Russell discards all "cleansing liquids" which contain rouge or nitric acid, and recommends the following course:—If the glasses have been used before they have to be soaked for a short time in a warm solution of common washing soda, rinsed well, and then left to drain and dry; if the glasses are new, the soda solution is omitted, and a simple washing substituted. Afterwards they are to be rubbed well on both sides with a mixture of old collodion one part, and methylated spirit one part, brought to a port-wine tint, either by age or the addition of free iodine, mixed with tripoli. Before use, it is always to be shaken up and then allowed to subside a few seconds, so that the heavy coarse particles which might scratch the glass may settle to the bottom of the bottle, and not come in contact with the glass plate. After being rubbed with this mixture and a piece of cotton wool, the plates are set aside until several are so treated; after which, they are placed in the screw holder, and the collodion mixture polished off with a rubber, made by cementing a piece of felt on to a large cork. After this they are to be further polished with another rubber made by covering a piece of wood with several thicknesses of flannel, and then with cotton velvet. Finishing with leather is altogether tabooed. This is a very brief abstract of Major Russell's instructions on this part of the subject.

Considerable stress is laid on the advantages and simplicity of the coating of gelatine applied as a couch for the collodion, and the minutest instructions given for efficiently conducting the operation. The advantages claimed for the gelatine coating are, that it not only prevents blisters and the film leaving the plate in developing, fixing, &c., but that it gives much greater certainty of clean negatives; and by masking slight scratches and defects in the glasses, prevents the waste of many which would otherwise be useless. The strength of the gelatine solution recommended may be from two to five grains to each ounce of water, with one drop of glacial acetic acid for each grain of gelatine. The object of the acetic acid is to coagulate and collect into filaments, which may be removed by filtration, a certain white opaque impurity present in all samples of gelatine, and of which it is very desirable for this purpose to be entirely free. A drachm of alcohol is added to each ounce to prevent decomposition. The strength of the gelatine solution, varying as we have said, from one grain to five, is to be regulated by the thickness of the collodion: a weak solution is sufficient for a thin collodion, but would be apt to loosen from the glass if a thick strong-bodied collodion were used, under such circumstances; therefore, a stronger gelatine solution is necessary: and it is recommended that, in coating with gelatine and with collodion, the solution may in each instance be drained off the same corner of the plate, by which means the thickest portion of the collodion film will be supported by the thickest part of the gelatine coating.

The chapter on this kind of collodion will be read with considerable interest. It is a singular and somewhat puzzling circumstance, however, that whilst the originator of the process attaches tho utmost importance to the advantages of a large quantity of bromide, Mr. Sutton, one of its most enthusiastic advocates lays it down as one of the primary conditions of success that no bromide whatever is to be used. In our own experiments we have certainly observed a marked improvement in delicacy and softness, as the result of the presence of bromide; and Major Russell intimates that the improvemeut may be distinctly observed by every addition of bromide, uutil it reaches as much as three grains to every five of iodide in an ounce of collodion. Regarding the collodion generally, and the bromides particularly, the major shall speak for himself. He says:—

"Almost any collodion will produce good results with tannin if properly managed, no matter how new and horny, or how old and rotten. Even should it be too old or too new to work well in tho wet process. it will still succeed. Some difference will, however, be found in the character of the resulting pictures, though not so great as in the wet process, and there will bo a great differeuce iu the sensitiveness. A new collodion is tho most sensitive, and in the writer's hands gives the proper red tone and vigour of negative perfectly, provided a strong solution of tannin be used. An old and powdery sample, on the other hand, even if rendered colourless by cadmium, besides being very insensitive. gives a palo grey image, which will not develop with quite so much vigour and richness or tone, and the film when varnished is soft and liable to injury, whereas that produced by a new and horny collodiou is, in harduess and durability, only inferior to albumen. A tolerably opaque film is advantageous, but not so necessary as iu other dry processes; plates prepared with tannin being little liable to solarization. Opacity should not be obtained by over-iodizing the collodion, but by using a thick sample.

"Simply iodized collodion may be used, but the preseuce of bromide greatly increases sensitiveness, intensity, and facility of development. Any collodion which is sensitive and gives good results in the wet process may bo rendered suitable for use with taunin in the following manner:—Dissolve sixteen grains of bromide of cadmium and four grains of bromide of ammonium in one ounce of alcohol s.g. ·805: if tho collodion is not iodized, mix three parts of this solution with five parts of the iodizing solution, and to one part of the mixturo add three parts of plain collodion. If the collodion is already iodized, add three parts of plain collodion to ono part of bromide solution, and mix three parts of bromized collodion with fivo parts of iodized collodion.

"Positive collodion will require less bromide, as it usually contains somo already; but the exact proportion of iodide and bromide is not of much importance. Tho addition of bromide of cadmium to collodiou iodized with iodide of potassium, produces, by double decomposition, iodido of cadmium and bromido of potassium: the formor impairs the fluidity of the collodion, and the latter, being nearly insoluble in strong alcohol, is almost all precipitated. If, therefore, tho preseuce of iodide of potassium is shown by turbidity on the addition of bromide, it will be botter to dissolve about two parts of bromido of ammonium, and one part of bromide of cadmium in the smallest possible quantity of alcohol s.g. ·816, and to add this solution cautiously until turbidity is produced. The collodion will be found to be very little altered in fluidity and stability, and, when cleared by subsidence, to havo retaiued euough bromide to improve it greatly for this purpose.

"Should any doubt be entertained as to the good effect of so large a proportion of bromide as that recommended above, it may be easily removed by experiment. Prepare thirty-six drachms of iodized and eighteen drachms of bromized collodion in two bottles, the iodide and bromide being in the same proportion in both, and the same plain collodion being used in both cases. Coat and excite one plate or more with the iodized collodion; then mix half a drachm of bromized with four drachms of iodized collodion in a small bottle, and proceed as before; pour away into another bottle, and mix one drachm of bromized with four drachms of iodized collodion, and so on, increasing the proportion one-eighth part each time, until equal quantities have been used. We shall now have nine differently constituted sensitive layers, varying by one-eighth in each case, from all iodide to equal parts of iodide and bromide. The residues, if all poured into one bottle, will be found to do very well for ordinary use. The plates, after being prepared with tannin, are then to be exposed a minimum time in a uniform light, using the same subject, and developed in the same manner, when it will be found that there is a rapid and regular improvement up to three parts of bromide to eight of iodide, and that further addition of bromide makes but little difference up to equal parts of each. Three parts of bromide to five of iodide will probably give about the best result; and it will be seen that this proportion leaves an ample margin both ways, to allow for disturbing causes, such as a little bromide or an uncertain amount of iodide in the collodion, if of unknown composition. The different proportions of iodine and bromine in various iodides and bromides, and peculiarities in the quality of the pyroxyline, might slightly affect the quantity of bromide required to give the best result. The use of a large quantity of bromide has a tendency to diminish the opacity of the excited film. Should this effect be produced to too great an extent, a little more iodide and bromide may be added in the proper proportion to the collodion. Bromide may not produce so marked an effect if a trace of nitrate of silver be left in the film; but, even if the presence of nitrate with the tannin appears to answer the same purpose as bromide, the use of the latter and the entire removal of the nitrate is for many reasons a preferable mode of treatment.

"If the collodion be purposely prepared for use on gelatine with tannin, the following will be found to be a good formula:—

Iodide of ammonium	2 grains
Iodide of cadmium	1 "
Bromide of cadmium	2 "
Pyroxyline, prepared by Hardwich's formula for negatives by the wet process	6 "
Alcohol, sp. gr. ·805	4 drachms
Ether (the best which can be procured)	4 "

This collodion will require to be diluted with more alcohol and ether if used to coat large plates. The salts of cadmium give great stability to the collodion, and are very soluble in highly rectified alcohol; but they render the collodion so thick as to be ill-adapted for producing a good uniform film on a large plate. Iodide of ammonium has an opposite effect, rendering the collodion unstable, but very fluid; hence, by using different proportions of the iodides and bromides of cadmium and ammonium, we can vary the quality of the collodion in the above respects at will."

A bath sufficiently acid with acetic or citric acid to redden litmus paper is to be used. A first washing in distilled water, is followed by thorough washing in common water, in which it is recommended that the plate should soak not less than half an hour. A bath of salt and water may be used if desired, but the plate should then receive another washing, even more thorough than for the removal of the free nitrate of silver.

The strength of the solution of tannin, Major Russell here suggests, may be varied from ten to thirty grains to the ounce, varying with the kind of subject, the light and the kind of collodion; the stronger the tannin solution, the more rich and dense the negative. With subjects having much contrast and in a good light, a strong solution of tannin is apt to produce too much vigour. The plate is to be rinsed with distilled water, and the back of it wiped dry before applying the tannin. This is to prevent the slightest absorption of common water or other impurities into the preservative solution. Spontaneous drying at a moderate temperature is preferred to artificial heat. The following description of the appearance which should be presented by the plate, when prepared and dry, will be interesting and useful:—

"When the film is dry, the surface should present a bright and highly-polished appearance. If the collodion has been from good pyroxyline, any dulness seen by reflected light is always the result of some kind of mismanagement, and is most commonly produced in one of the following ways:—First, by adhesion of insoluble salts of silver, from the plates having been placed in hard water, or salt and water, before the nitrate was sufficiently removed by distilled water; secondly, by the film having been too much dried before immersion in the nitrate bath; and thirdly, from the use of over-iodized collodion. In the first case, the precipitated matter will appear in smears, following the direction in which the plate entered the hard water, or in which the water first flowed over it. In the second case, the deposit will probably be confined to the neighbourhood of the two edges which were upwards when the collodion was poured off, which edges will look blue and transparent. In the third case, the loose iodide will be distributed more uniformly over the plate, without the transparent edges at the upper end. In the first case, if the precipitated matter is of small amount, it may be entirely removed, and the plate made practically as good as if no deposit had been formed on it, by attaching the glass to the holder, and rubbing the surface with a tuft of clean dry cotton wool. This should have a handle formed by binding round a part of the wool with string, the end of which should form a loop, to hang on a nail in the edge of a shelf or other convenient place. If kept for this purpose only it may be used for a great length of time. In the second and third cases, the plate will be improved by removing the loose iodide in the same manner; and in the second case, the picture will be good on that portion of the film which retains its opacity, and is not rendered more transparent by the loss of iodide of silver. In the third case, a good result cannot be expected, especially when the amount of loose iodide is large, and has marked the film by bursting out irregularly.

"In all cases it will be well to brush the surface of the excited plate with the cotton wool before placing it in the slide, to remove any particles of dust which may be present. If a new and horny collodion was used, pretty hard rubbing will cause no injury, especially when the solution of tannin was somewhat concentrated."

The chapter on development is full of most valuable suggestions, by attention to which a complete power over the character of the negative may be obtained, even in cases of over or under exposure. A chapter on producing transparencies, for which tannin plates are pre-eminently suited, follows; and the book concludes with a chapter devoted to some remarks on dry processes generally, on which some excellent hints are offered.

The chief objection which has been urged against the tannin process is its slowness. This, however, can scarcely be regarded as a real objection. Unless instantaneous results can be obtained, or at least an approximation to the sensitiveness of the wet, the exact amount of exposure cannot be regarded as a matter of importance in landscape work. If an exposure of two minutes be necessary with one process, it cannot matter much that another process shall require three or four minutes. Instantaneous results have been obtained by means of the collodio-albumen process, and the aid of a hot developer; and it becomes a question whether heat may be applied in developing a tannin negative; we fear that it would be found unsuited to the character of the plates. For many purposes there can be no doubt, however, that the tannin process will always be found useful, and such a guide in its application as the manual before us, is most desirable. Much of the information, based as it is upon careful experiment and a thoroughly intelligent apprehension of the precautions necessary in the manipulations of the dry processes generally, cannot fail to be of the utmost value to all dry photographers, to whom we cordially commend the book.

Scientific Gossip.

It is necessary that those of our readers who practice their art in the City, should be warned of the danger they incur by using the water from some of the pumps, which were placed where they now stand when London was less crowded and the wells less contaminated than they are at present. Dr. Letheby, the analytical chemist to the Commissioners of Sewers, has lately given a fearful account of their impurities, compared with the New River water, with which the greater part of the City is otherwise supplied; the quality of these wells is most objectionable, for, instead of an average of only 19 grains of solid matter per gallon, the water contains from 20 to 127 grains. The quantity of organic matter in them ranges from 1·5 grains per gallon to 8·8; the common salt from 2·7 to 25; the alkaline nitrates from 2·1 to 24·6; and the combined ammonia from 0·5 to 2 grains per gallon. These results show that the City pumps are not only charged with decaying organic matter, but also with the saline products of its oxidation; the ammonia, for instance, is a sign of present putrefaction, and the alkaline nitrates of past; besides which the existence of so large a quantity of common salt is suggestive of the filthiest impurities, as, for example, the fluid matters discharged from the human body, and the percolations from cesspools and sewers. Most of these waters are bright and sparkling, and they have a cool and agreeable taste. They are, therefore, much sought after for drinking purposes; but the coolness of the beverage and the briskness of its appearance are dangerous fascinations, for they are both derived from organic decay. Dead and decomposing matters have accumulated in the soil, and have been partially changed by its wonderful power of oxidation, and thus converted into carbonic acid and nitre. These have given to the water the agreeable qualities which are so deceptive. In reality, the water from the City pumps is far worse than that from the muddy river from which it is in great part derived; indeed, it may at any moment become charged with the active agents of disease, for no one can say when the salutary influence of the soil may fail by being worn out or overtaxed, and then the putrid organic compounds will pass into the wells unchanged. Many of the pumps are in close proximity to the fat graveyards of the City, and it is more than probable that all of them derive a portion of their water from these sources, for they are the principal gathering grounds for the surface springs; in fact, they are the only open spaces through which the rain can percolate to reach the shallow wells. We need not dilate upon the great danger to health which is certain to arise from the habitual use of such water as this, as a beverage, even when it is mingled with some alcoholic liquid "to take the rawness off." City photographers are too sensible men to continue drinking such vile stuff after reading this account; but for fear any of them may think it good enough for photographic purposes, we take this opportunity of warning them against its employment in any form. The large amount of organic matter would fasten upon the silver and fix it on the surface of their paper in an insoluble form, where it would not cease to darken until the beauty of the print was irretrievably gone; the nitrates by their oxidising properties would be very dangerous compounds to leave in the pores of a delicate silver print when we know how very susceptible this is to vanish, the silver on the surface being almost in a position of unstable equilibrium, and liable to have its balance destroyed by the smallest atmospheric or aqueous impurity, when it eagerly takes the chance of fading away: whilst the ammoniacal compounds would not only have a similar effect to the above but would exert their own specifically injurious actions. Upon the whole we think that the less a photographer goes to a City pump the better: it would be far less injurious to make use of Thames water at London Bridge; this, after the suspended impurities were separated by a filter or by decantation, would not have anything like the injurious action of the water from any of these pumps. In order that the worst of them may be known and avoided, we append the names of some of the most impure. They stand in the order of their foulness as follows:—Bishopsgate Street Without, Aldgate pump, Cock and Hoop Yard, Houndsditch, Bishopsgate Street Within, Bride Lane, Bow Church Yard, Fenchurch Street, Little Britain, Basinghall Street, Chequer Yard, Dowgate Hill, Bell Yard, Gracechurch Street, Idol Lane, Ironmonger Lane, Bartholomew Lane, Cornhill, Bowling Square, White Lion Street, Half-moon Passage, Great St. Helen's, Gutter Lane, Honey Lane Market, Guildhall Buildings, and Glovers' Hall Court. Dr. Letheby promises us analyses of the remainder of the pumps; and if, as is most likely, they turn out to be equally foul, we will take care to lay the results before our readers.

A chemist, who, however, has not given his name, has recently published an account of a series of experiments which he has made on the preparation of gun cotton. The results he has arrived at may be summed up as follows:—The smaller the quantity of cotton wool operated upon, the more easy it is to prepare a good gun cotton. An ounce of cotton wool he found was as much as could be manipulated with safety. The proportions found to give the best results, were one ounce of cotton wool, 16 ounces of nitrate of potash, 12 ounces of English sulphuric acid (sp. gr. 1·84), and 12 ounces Nordhausen acid. Five minutes in this mixture was found to effect the change in the cotton perfectly. A longer exposure was not only useless, but mischievous. The temperature at which the action of the mixture goes on best is from 154° to 160° F.

A few more specimens of glass have been sent to our office to be examined in the spectroscope, we will describe them in the same manner as we adopted with the previous specimens described at pp. 349 and 373 of this volume.

13. (No. 1. B. K.)—A light orange yellow glass. This is of the same character as No. 12, but rather darker. Examined with the spectrum it was shown to entirely cut off the lavender and violet rays above the fixed line G; from F to G were likewise considerably diminished in intensity, but below F the rays were scarcely obstructed at all. In strong light considerable quantities of photographically acting light would get through the glass, and in weak light some would penetrate, so it cannot be recommended to continue the employment of this quality.

14. (No. 2. B. K.)—This is a very good kind of glass for ordinary employment in the dark room. It is of a deep orange brown colour, and except in very strong sunlight allows the passage of no chemically acting rays whatever. If the light, however, be very concentrated, traces of the green and blue rays are seen to struggle through, but these are in such small quantities that, if the window of the room be in a position that the direct light of the sun does not fall on it, and it be not more than a few square feet in size, no danger need be apprehended from its use. It would, however, be preferable to get a kind of glass such as that described at p. 373, No. 11.

15. J. L. M.—This is a very curious glass, being of a dark smoke colour. It scarcely seems to alter at all the colours of natural bodies observed through it. In the spectroscope the blue of the spectrum is nearly obliterated, but the indigo and violet are not acted upon so much. As far as the photographic value of this glass is concerned, it is positively worthless; the possessor might as well attempt to prepare his plates in the open air as to trust to this glass for protection.

16. X. Y. Z.—A deep bottle green glass, which in the instrument cuts off all the most refrangible end of the spectrum, leaving however a band of blue above the green. The other rays suffer little change; the green however appears to be intensified. This is not a good glass for the present practice of photography. In the olden times, when bromine was unused, it would have done, as it is opaque to all the iodic acting rays; but now, bromine is in such

vogue, it would admit plenty of injurious light about the line F.

17. H. Mac. D.—This specimen of glass is of a brown colour, similar in its appearance and action on the spectrum to No. 6, p. 349. As it lets all the green rays through, and a trace of the blue, it would be almost useless if bromine is employed in the collodion, whilst it would not be safe with iodized collodion, as in strong light some of the violet and indigo rays can get through.

ACCIDENTS WHICH OCCUR IN ENDEAVOURING TO OBTAIN MAXIMUM SENSIBILITY.

BY M. M. A. GAUDIN.

A strictly neutral silver bath causes a general fogging of the picture at the moment of development. It is absolutely necessary to acidulate the bath, but as little as possible, to obtain the maximum of sensibility.

Nitrate of silver fused and crystallized anew gives a suitable bath at once, but much of the crystallized nitrate sold is seldom pure. It is therefore necessary, when dissolved and saturated with iodide, to add to it a very minute quantity of carbonate of soda, and after filtration, to acidify it with two or three drops of nitric acid to the quart, and a still larger proportion of acetic acid is used.

Having resolved to acidulate only with nitric acid, to avoid the formation of acetate of silver, which is sometimes so objectionable, I was very much astonished to find this acetate of silver which prevented me from working a whole day.

Having prepared a new bath, first neutralizing it with carbonate of soda, and acidulating it with nitric acid, I poured it into my gutta-percha bath, without having first rinsed it out. I was greatly surprised upon examining the sensitized collodion film, to see it covered with a multitude of salient points, which remained after agitating the plate in the bath, and these points formed a multitude of holes in the picture which was riddled like a sieve. Upon examining the film under a powerful magnifier, I found that each white point was formed by a white crystal imbedded in the collodion film. I at first attributed this result to the collodion; but upon making use of an entirely different sample, I found the effect to be just the same. It must therefore arise in the bath, and upon examining the gutta-percha I found it covered with small microscopic crystals, which were easily detached from its sides by agitation, and became imbedded in the collodion film while it was still soft. Filtering the bath again diminished the number of these crystals greatly, but did not cause them to completely disappear. I then thought of acetate of lead which dissolves acetate of silver, and the addition of a small quantity of the salt of lead caused the crystals to disappear as if by magic. Their production was caused by a small quantity of the preceding bath acidulated with acetic acid being left in the gutta-percha, which had undergone decomposition upon the addition of the new bath free from acetic acid, and which doubtless possessed the property, like acetate of lead, of dissolving a small quantity of acetate of silver.

I have recently experienced an accident no less extraordinary than the above. After having tried a new bath with my little apparatus, I recognized in it an extraordinary degree of sensibility, the pictures obtained were of an unexceptionable purity, with skies of great intensity; while in operating with the same collodion, the same nitrate bath, and the same developing agent, the stereoscopic negatives were weak and fogged. The *fogging* was caused by parallel and circular striæ, which I could not attribute to negligent cleaning of the plates, as they had always been finished with great care in rubbing them *lengthwise*.

I should add that this difference between my little apparatus and my stereoscopic camera continued for six weeks constantly, so that at last I was disposed to believe that the camera of this apparatus possessed a malevolent influence, so far was I from suspecting the real cause.

Having previously made use, successsfully, of gutta-percha dishes, with the same apparatus, and the new dish I employed having through excess of precaution been covered with lac varnish, I had no uneasiness on that score; yet all my non-success was caused by that very dish.

Gutta-percha alone is a very bad material of which to make nitrate baths: it contains naturally much tannin, and nothing can be worse for silver baths than a reducing agent, however small in quantity. It is very well known to practised photographers that new dishes of this material are worthless at first; but there are some kinds which are altogether unfit for use. It was one of this kind that I had employed in the present case: its varnish seems to have disappeared. The bath maintained its clear condition, but the pictures never appeared without making me regret that I had ever employed it.

However, to decide the matter, I made a conclusive experiment, taking into account that the bath for my little apparatus, is a porcelain dish, while that for stereoscopic apparatus is a gutta-percha dish. With a new bath, slightly acidulated by nitric acid, my little apparatus gave me splendid proofs constantly; the first stereoscopic proof was passable, but with a feeble sky; the succeeding proofs were feebler and feebler, and fogged. I then changed the bath in my porcelain dish by putting into it that which was in the gutta-percha dish, and then the proofs taken in my little apparatus were also *fogged*.

By this decisive experiment, I at length recognized that the repeated failures, which I attributed first to the collodion, then to the cleaning of the plates, and then to the apparatus, were actually due to the gutta-percha dish. After that I decided that henceforth I should never employ gutta-percha dishes or baths to contain solutions of *nitrate of silver.—La Lumière.*

PHOTOGRAPHY ON MONT BLANC.

Last year, M. Bisson, whose photographs have earned him a well-merited reputation, attempted to scale the "giant of the mountains," with all the apparatus necessary for photographic operations. But the weather was so bad, that he had to abandon the attempt for a time, and this year he has resumed the undertaking.

On the morning of Monday the 22nd of July, he arrived at Chamounix, at the foot of Mont Blanc. The weather appearing favourable, the ascent was decided upon. The entire host of travellers which this beautiful summer has attracted to Chamounix, together with the honest inhabitants of this little village, who seem to live but six months out of the twelve, assembled to witness the departure of the intrepid photographer in company with his guide, Auguste Balmat—the worthy descendant of him who first placed his foot on the summit of Mont Blanc—and a company of five-and-twenty porters, who, in relays, were to carry "up yonder" the cameras, glass plates, collodion, and all the photographic paraphernalia. Then came the leave-taking, the shaking of hands, the oft-repeated cautions, counselling prudence, wishes of success, &c., and at the moment of starting a salute of cannon was fired. The echo flew from peak to peak, the sound becoming weaker and weaker, until lost in the distance, seeming to warn the travellers of the length of their journey, and to stimulate their courage.

At nine in the evening the party arrived at the *Grands Mulets*, the first station, beyond which M. Bisson was unable last year to proceed. At this point a Bengal light was burned as a signal, to which Chamounix responded by salvos of miniature artillery.

While seeking a few hours of repose, the travellers were soon awoke by the noise of the wind, blowing a perfect gale. Balmat, disconcerted at this *contretemps*, advised that their departure should be delayed. After the lapse of a couple of hours the violence of the wind abated, the weather cleared up, and it was resolved to proceed. Carefully holding each other by the hand, they, taking their lanthorns, resumed the ascent.

At six in the morning they reached the *Grand Plateau.* At this hour the weather was splendid. For a time M. Bisson entertained the idea of profiting by the serenity of the atmosphere to take some views of the strange and grand scenes by which he was surrounded; but the fear of losing so favourable an opportunity of arriving at the summit, from which they were still six hours journey distant, induced him quickly to resist the temptation, so pushing on, they soon arrived at the *Petits Mulets.*

But the courageous little party had scarcely arrived at this summit, when a fearful squall overtook them, that soon became a complete storm, which raised such a cloud of snow as soon to envelope the party in complete obscurity, and it was only with extreme difficulty that they succeeded in finding a shelter.

While sleep, which, as is well known, is mortal, in these elevated regions, soon overcame the whole party, M. Bisson requested Balmat, the guide, to pitch his tent on this spot. The guide, looking at him with unfeigned surprise, exclaimed, "Do you wish to see Chamounix ever again? we have only just time, and by God's help, to regain the *Grands Mulets,* the avalanches will soon be coming down, and the snow will not render this place safe very long."

Groping their way, for they could not see ten paces before them, the party endeavoured to retrace its steps, clinging to each other, and in this fashion they descended a slope of 45 degrees, some six hundred yards in length. Walking, or rather sliding, somewhat quicker than they desired or found agreeable, they soon reached the corridor, and then the *Grands Mulets.*

They were now at the same spot from whence they started in the morning.

The avalanches began to descend on all sides with terrific uproar. Calling the roll, every one of the party responded to his name; but two of the men were almost blind, and three others were not in a fit state to proceed. M. Bisson, and even Balmat himself were oppressed with severe headache. Nevertheless, they would not abandon their firm resolution, but determined to wait for fair weather, and fortunately, they had not to wait very long.

The wind abating, a consultation was held, whereupon it was determined to send the disabled back to Chamounix, and obtain a reinforcement of seven men. This required a long halt at the *Grands Mulets* for the rest of the party, longer than at any other portion of the journey. But about nine o'clock in the evening, voices were heard singing; it was the reinforcement from Chamounix approaching, which arrived full of mirth and courage. Their arrival was joyfully acknowledged. The evening was spent cheerfully, and the spirits of the whole party reanimated. At midnight the sky became clear, and illuminated by the rays of a full moon. The signal to advance was given, and the party proceeded to make the ascent.

At seven o'clock in the morning of the 24th they regained the *Petits Mulets;* at eight they attained the summit. The party was seen from Chamounix, for the echoes of their cannon were heard, even at that elevation.

But it was not yet time to shout victory! For M. Bisson had not yet fought his battle. His most difficult task had now to be commenced; to practise photography at an elevation of 16,000 feet above the level of the sea is certainly not child's play.

It was first necessary to erect a tent, beneath which, sheltered from light, the plates could be coated, the operator trembling neither from cold nor emotion, and then to sensitize them with steady hands in the nitrate bath. Now the disposition to sleep was invincible; every one was overcome by it. But as Balmat and M. Bisson, notwithstanding his delicate constitution, both resisted, they alone, unpacked the baggage, and arranged the apparatus. The tent was erected, the camera placed on its tripod, the plate coated, sensitized, exposed, and a view taken. What a view! what a panorama! It was now necessary to develop the picture, but there was no water at hand for washing the plates. They had reckoned upon the snow, and upon melting it with the heat from lamps; but in this rarified atmosphere they would only burn with the feeblest of flames. Amid his despair the baffled photographer was involuntarily reminded of the exclamation of the veteran of the Russian campaign, "The fire freezes." A man was placed at the lamps to keep them burning, he fell asleep. He was replaced by another, who did the same. At length M. Bisson himself succeeded in obtaining sufficient of the precious element. Hastening to his tent, at the door of which Balmat alone remained standing, he finished his negative. Now he might have shouted victory! But no. After a repose of two hours he recommenced operations, he would not go back without three pictures; he succeeded in obtaining them, two were good, one was passable.

The baggage was now repacked, the sleepers awoke after a good shaking, and the descent to the *Grands Mulets* commenced. They must hurry back to Chamounix, all but the photographer. At this point he must take fresh views, although impatiently expected in the valley below, where a grand fête awaited his return. The village was illuminated, fireworks exhibited, every body appeared over-joyed and happy, but none more so than M. Bisson.

ON THE PREPARATION OF "PHOTOGENE."

BY A. GAUDIN.*

I propose to give the name "photogene" to any sensitive compound containing iodide of silver with excess of free nitrate of silver. Gelatine can be mixed with nitrate of silver in any proportion, is the most convenient substance for the purpose.

To prepare this compound, dissolve in a flask, at a gentle heat, 1 drachm of white gelatine in 10 drachms of water. When it is all dissolved add half-a-drachm of nitrate of silver. Next, dissolve in another vessel 12 grains of nitrate of silver, and precipitate it as iodide by the addition of a soluble iodide. Collect the precipitate upon a filter,—wash it well, and then add it to the argentiferous solution of gelatine. The mixture must then be beaten up for some time until the liquid becomes homogeneous, and when spread upon glass resembles in appearance a sensitive film of iodized collodion. Before employing the photogene warm it, and filter it through a glass funnel, having in the neck a tuft of cotton wool, through which you have first filtered a little alcohol in order to remove greasy matter, and afterwards water to wash out the alcohol and damp it properly. The filtered opaline liquid is then used, while still warm, for coating the glass plates, which have been previously cleaned with a little albumen.

The photogene prepared in these proportions is extremely fluid, and flows over the glass plate as readily as collodion. Its great fluidity, favoured by its warmth, causes it to leave an infinitessimally thin film upon the plate, which is as structureless as the glass itself. When the glass has been coated it must be placed vertically to dry, with one corner upon blotting-paper. If you increase the proportions of gelatine and iodide of silver, you must use the photogene hotter, because it is necessary to produce as thin a film as possible. As soon as the photogene is cold, it becomes set, and the plate may be exposed in the camera, but you must not proceed to the development until the film is so dry as not to stick to the finger.

The image is developed by covering the glass with a concentrated solution of tannin, filtered. It comes out in general without silver, but it is better to add a few drops of nitrate of silver soon after applying the tannin.

By proceeding thus the picture exactly resembles one

* M. Gaudin's researches and discoveries in this direction appeared in *La Lumiere* about the same time that the announcement of Captain Dixon's patent, and also a letter on the same subject by Mr. Bellini, appeared in our columns. We were unable from the crowded state of our columns to publish it at the time; but as M. Gaudin is renewing his researches, and the subject is interesting, we now insert it.

taken upon albumenized glass. But the gelatine swells, and if the sensitive film is not extremely thin, its surface would become uneven, which would injure the details.

The image comes out at first red, and afterwards passes to an intense bistre tint. This photogene is nearly as slow as albumen. The image is also very long in developing.

The compound ought to be prepared and used in a yellow light, and the bottle which contains it should be screened from daylight. If light is allowed to act upon it, the photogene turns brown, and requires to be revivified. This can be done by adding to it a few drops of bromine water, which, after agitation, restores to it its clear yellow colour.

This photogene, spread upon a glass, and dried spontaneously, can be used in the same way as albumen, for printing glass transparencies.

In order to fix the picture with hyposulphite it must be used very weak—strength about five per cent.—for it tends still more than the tannin to render the film uneven. After an abundant washing, dry the plate by artificial heat, and varnish it in the usual way.

Photogene with Collodion.—I have prepared two photogenes with collodion, one with iodide, the other with chloride of silver as a basis.

The photogene with iodide of silver is sometimes as sensitive as a wet collodion plate. It may, therefore, be used for taking negatives upon paper, in the camera; or enlarged positive prints with a short exposure, and upon very large sheets.

The photogene with chloride of silver may be used as a substitute for ordinary positive paper for small pictures. Amateurs will find it very convenient for that purpose.

The photogenes with collodion exhibit different properties, according as they are applied to glass or paper. Upon glass the image develops very feebly and superficially. The photogene is almost impenetrable to developing agents; and this is unfortunate, because, but for that, it would realize the long-sought-for dry collodion. We shall arrive at that, no doubt, by imparting to it the porosity which it acquires when spread upon paper.

I prepare the collodion photogene by dissolving nitrate of silver in hot alcohol with a few drops of water, and adding this alcohol to common plain collodion. The mixture must be well shaken in order to incorporate the nitrate, which is only slightly soluble, with the collodion. While shaking the bottle add to it from time to time a few drops of common iodized collodion, which renders it more and more opaline. As soon as the mixture, when spread upon glass, exhibits the appearance of a homogenous film of excited iodized collodion, it is ready for use, provided the nitrate, of siver is in excess. To try this you must make an experiment upon paper thus:—

Spread upon a sheet of paper some of the photogene, exactly in the same way as upon glass. When the paper is dry lay a negative upon it, and holding it in the hand upon a support, expose it rapidly to diffused light. If the nitrate is in excess, an intense black can be quickly developed upon the paper with a little weak gallo-nitrate of silver; otherwise the compound is worthless, and you must continue shaking the bottle, and adding silver as before.

When the operation succeeds well the photogene is of exquisite sensitiveness. You must coat the paper with it in a yellow light, or at a long distance from a candle having a yellow screen, or you will not preserve the purity of the whites, for you are working here with a process which is much more rapid than chloride of silver printing.

On the day when I worked with a very sensitive iodized photogene, I obtained proofs in thirty seconds by the light of a candle, and in one minute behind the yellow glass of my laboratory window. And in order to print from a negative by diffused light, one second was a great deal too much, for the image came out instantly in very weak gallic acid.

The photogene adheres sufficiently well to paper to resist all the rubbings which it encounters among other sheets in a dish; but on rubbing a proof strongly with cotton wool it became weakened in that part, which makes me think that the adherence of the photogene to *sized* paper is hardly sufficient. It will be necessary, no doubt, to use unsized paper.

The collodion photogene with chloride is prepared in a similar way, only the collodion must contain chloride of ammonium.

On adding nitrate of silver to gelatine it is nearly sure to become opalescent, on account of the hydrochloric acid which it commonly contains; but that does not matter. If you use a chloride it must not be chloride of zinc, because that coagulates gelatine with great energy.

The collodion photogenes can be restored, when damaged by exposure to light, in the same way as the gelatine photogenes, viz., by adding a few drops of bromized ether or alcohol. In order to convince myself of this, I have made a direct experiment. After having blackened a photogene by exposure to sunshine in a plate, I restored the active yellow tint by adding a small quantity of bromine.

PHOTOGRAPHY WITHOUT LIGHT.

The name photography (light drawing) has been given to our art on the supposition that it is by the presence and action of light that our pictures are made. The name has proved a very good name, no objection has been made to it, it answers to the notions of most people. Yet in a scientific point of view it implies a falsehood, it is almost a *lux a non lucendo.*

Scientific research has demonstrated that the light which renders objects visible and the light for which our eyes are made is not the force or even a part of it which so wonderfully fixes the forms of things on our chemicals. Our mysterious friend is far more subtle and more spiritual—we scarcly know her by name, and are only able to recognise her in the work she performs. We have eyes for light, and ears for sound, but what sense informs us when *actinism* is present?

Photographers are able to know from their own experience that actinism and light are not the same thing. The yellow paper or glass of the dark room lets in the light but stops the actinism in transitu. Perhaps if we had a sense which could observe the actinism on the glass or paper we should find it all on the outside, like dirt on a filter.

Place a yellow glass before the camera tube, and you can get no picture, but not because there is not light enough. Or, instead, use a deep blue glass, and you may have a picture, although no visible light got through to the plate. If the sun should suddenly stop shining, but emit only actinism, although we should be in pitchy darkness, we might still produce all the chemical effects of photography.

Now I think it quite useful that these facts are so, for it gives us the opportunity of using our eyes, where otherwise we could not. If our chemical preparations were ten times more sensitive than they now are, and actinism could not be separated from light, we would not dare to have even the glimmer of a candle about our developing. But as nature has ordered these things we may have chemicals a hundred times more sensitive, and yet have a brilliant light of day over all our work.

Thus far we have made little use of these facts further than to let light into the dark-room through a yellow screen. But why not go further? I offer a few hints:—

If the cap of the camera tube and the back of the shield be a pure yellow glass, the focus may be taken on the sensitive film itself. Or rather let the whole plate shield be of yellow glass, or even the camera box and all.

Let the camera box be made of yellow glass, enclosing the bath and developer, so that the entire photographic process may be carried on in open sunlight!—*American Journal of Photography.*

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 21*st August*, 1861.

M. Gaudin in seeking to establish a comparison between his *Photogene* and the tannin process of preserving dry collodion plates, finds that when a wet collodioned plate required, under the best possible conditions, an exposure of six seconds, his photogen, which had been on the glass plate for three quarters of an hour, after an exposure of thirty seconds gave a weak negative, indicating that the exposure should have lasted sixty seconds, and thus showing that his photogene is at present ten times slower than wet collodion; but supposing he had a light four times stronger, a plate prepared by the tannin process requiring an exposure of nine minutes, is twenty times slower than wet collodion, and twice as slow as a half-dried photogene film; and he thinks, that in all probability, dry photogene would have proved as rapid as a dry tannin plate.

It remains to be ascertained whether the photogene will keep long in a dry state, and retain its sensitiveness. A preparation with which it suffices to coat a glass plate, which may be exposed immediately or in the course of an hour, without requiring to be immersed in a nitrate bath, appears a considerable step in advance; but means must be found of giving to this photogene a high degree of sensibility, and of employing it in the dry state like other collodions.

The problem M. Gaudin is engaged in solving is of so much importance to photographers, that his progress to its successful solution will be watched with much curiosity and interest.

The spontaneous decomposition of gun-cotton, a question of much interest to photographers, has recently been the subject of careful research on the part of M. de Luca. He obtained some gun-cotton in Paris in 1859, enclosed it in a bottle which was kept sheltered from the action of light, in a cupboard in the chemical laboratory of the Faculty of Sciences, Pisa. Its spontaneous decomposition took place during the summer of 1860, with the disengagement of nitrous fumes which attacked and corroded the cork of the bottle. The product of decomposition had a white aspect, slightly yellow on the outside, was pasty and glutinous: it formed an emulsion with cold distilled water: this emulsion passed slowly through the filter; filtered, it was limpid, and reddened litmus paper; in contact with copper and sulphuric acid, it gave off nitrous fumes; and was coloured deep yellow by potash or ammonia; it reduced the tartrate of copper and potash; in contact with an aqueous solution of iodine, it did not become coloured; when heated with sulphuric acid, it became of a deep brown colour; it gave a precipitate with excess of lime, and was also precipitated by chloride of silver, in presence of a small quantity of ammonia; when mixed with eight times its volume of alcohol, it gave a flocculent precipitate. The decomposed gun-cotton kept under a glass receiver at the ordinary temperature, in presence of concentrated sulphuric acid, became perfectly white, could be reduced to powder between the fingers, and lost about 38 per cent. of its weight. The flocculent substance precipitated by alcohol, collected upon a filter, washed with alcohol, dried in presence of concentrated sulphuric acid, is amorphous, almost opaque, friable, and of a gummy appearance, and dissolves readily in cold water; this solution is precipitated by acetate of lead, and reduced by tartrate of copper and potash. The modified aqueous solution of cotton, evaporated on a *bain marée*, deposits a substance which becomes spongy, light, white, friable internally, adherent to the fingers externally; which is soluble neither in ether, nor in a mixture of ether and alcohol, and only partially in alcohol; when this alcoholic solution is evaporated a residue is obtained, which reduces easily and abundantly tartrate of copper and potash. The portion insoluble in alcohol, left in contact with moist air, assumes the aspect of an extremely dense solution of gum; the modified cotton is attacked by warm nitric acid, with the disengagement of nitrous fumes, and the production of a yellowish substance soluble in water, and precipitable by acetate of lead, nitrate of silver, and nitrate of mercury.

The remarkably fine season we have been favoured with has attracted large crowds of visitors to Mont Blanc, among others, the distinguished photographer M. Bisson, who has fortunately succeeded in taking some views from a point near the summit of the mountain. Proofs of these negatives will doubtless be obtainable before long, and will assuredly excite the greatest interest in the photographic world.

SUNDAY PHOTOGRAPHY.

Sir,—I was much pained and surprised on reading in your excellent journal of the 16th inst., under the heading of "The Photographic Nuisance," the following paragraph:—

"We are the sworn foes of intolerance, and utterly deny the right of the law to interfere in questions of conscience." Nothing can, in my opinion, be clearer than the Fourth Commandment; and it is impossible to say that we are not bound to observe it without invalidating the other nine. If it be, as you say, a mere matter of conscience, so is drunkenness; and I think you will scarcely be bold enough to assert, that because a man tells you he sees no harm in getting intoxicated, he should not be fined for the offence. My own opinion is, that it is a disgrace to our legislature that not only the keepers of Photographic Dens, but of Gin Palaces, Tobacconists, *et id genus*, and more, should with impunity be allowed to desecrate the Sabbath. The declaration of our Saviour, that the Sabbath was made for man, cannot by possibility be made to extend beyond works of necessity; and if men have *no consciences* of their own, there can be no valid reason why they should not be legally prevented from outraging the feelings of those who have.—I am, sir, your most obedient servant, B. Jones.

[Polemical questions are not suitable subjects for discussion in our columns, but we willingly insert anything calculated to repress the practice of Sunday Photography. We must re-assert, however, our conviction that the law has no right to interfere in questions of conscience; and that in regard to drunkenues, the case quoted, the law has no right to interfere except so far as it trespasses on the comfort of the community, and becomes, as the enactment phrases it, "drunk and *disorderly*." And it is just in such a case where Sunday Photography becomes a public nuisance, that we conceive the law has a right to interfere. We should wish to see and aid a public expression of opinion from all respectable photographers, on such a subject. Still, a breach of the Fourth Commandment until it becomes an overt act, does not, we conceive, come under the consideration of any human law.—Ed.]

Proceedings of Societies.

Brook Green Photographic Society.

Inauguration Meeting, August 1, 1861. Professor Muddle, in the chair.

The Chairman, after stating the objects of the Society, introduced Mr. Fuddle, who read a most interesting and elaborate paper upon "A process of obtaining instantaneous photographs without any apparatus or chemicals whatever." The very title of the paper promised an exciting evening. We can only give a brief abstract in our present impression owing to the crowded state of our columns.

The learned gentleman explained that although he certainly considered he had a right to claim the originality of the process as applied to photography, the first idea was suggested to him by a well-known fact that had, he believed, been rather widely circulated of late by the press. The fact he referred to was that "by merely pouring boiling water into Fusbos' Kaffogen, from one cup to a hundred gallons of delicious coffee may be instantaneously produced." It would be clear to any one acquainted with the subject that a precisely analogous process might be employed to produce any number of delicious photographs, by merely substituting, *in the proper manner*, for the boiling water, or agent for transmutation, a ray of light, and for the kaffogen, or receptacle, a glass plate. This was what he (Mr. Fuddle) was happy to say he had been able to effect to his entire satisfaction. The paper then entered largely into the valuble results that must inevitably arise from such a process, the details of which were not explained, and the learned author sat down amidst great applause.

Mr. Blacksheep regretted that the time of the meeting should be wasted in discussing a paper which he could only compare to the "Comedy of Errors." The whole theory was wrong, the deductions false, and the asserted results impossible. He would have considered such rubbish unworthy of his notice, but that he owed it to himself to refute the assertion that Mr. Fuddle was the discover of the process. It was known to all present that the invention was the result of his (Mr. B.'s) labours, and indeed for some years past he had constantly used it with perfect success.

Mr. Twaddle entirely disagreed with the last speaker. He considered the paper a very valuable one, practical and sound. He was affirmed in this opinion by the abuse bestowed upon it by Mr. Blacksheep.

Mr. Mumble complained that he had been long unsuccessfully trying to catch the chairman's eye.

The Chairman said it was no fault of his. His eye was always at the disposal of the meeting, but he could not be responsible for the maladdress of individual members who were unable to catch it.

Mr. Mumble replied that the Chairman's urbanity was too well known for it to be supposed he meant to fix any blame on him. The fault lay in the incomplete lighting of the room. He thought that the illuminating powers of gas had now been sufficiently established to justify the council in sanctioning its introduction, as soon as the funds of the society would permit.

Mr. Blacksheep was surprised such a suggestion should be made. The pernicious effects of gas on works of art were well known. It would be pitiable if the art treasures with which their walls might be covered should be destroyed by careless inattention to such matters. He had written a book on the subject.

The Secretary reminded the last speaker that at present the walls were only covered with whitewash, upon which gas was not known to have any destructive action, and the terms of their lease secured them the right to have it restored annually at the cost of the landlord.

After a few words from other members,

Mr. Fuddle remarked, that although the meeting appeared to be adverse to the introduction of gas, he was sure that, as photographers, they would not object to a better light; he therefore moved "that the secretary do snuff the candle."

The motion having been seconded and put from the chair was carried; when

The Secretary said that agreeably with the wishes of the meeting he had entered the motion in the minute book, but he, must respectfully decline to comply with its provisions. There were no snuffers.

Mr. Blacksheep felt indignant that the funds of the society should have been squandered, he knew not how, and that articles of the first necessity were still unprovided. However, as this was the case, it appeared to him that the council neglecting their duty did not justify the Secretary in neglecting his. The meeting had formally passed a motion embodying an instruction to him. It was his duty to obey those instructions whether he had the means afforded him of doing so or not. That was his notion.

Corporal Trim observed that as it appeared a question of discipline, he might be allowed to say a few words. Formerly, when England was in danger, he had been a militia-man. Many present had seen him on the Green. He was now a volunteer. When officers gave an order, that order must be obeyed. He was quite sure that was the rule of the service.

The Secretary remarked he was an officer of the society which was giving orders to him.

Corporal Trim was aware of this fact, which, of course, altered the matter entirely.

The Chairman said he was not a military man; but he was going to volunteer—(cheers). The meeting should not interrupt—he was going to volunteer a proposal by which he believed the wishes of the meeting might be met notwithstanding the difficulties which had arisen.

Mr. Blacksheep objected to any compromise. The Secretary must snuff the candle; any other course would stultify the meeting.

Mr. Fuddle, as originator of the motion, begged to remark that the excuse of the Secretary was frivolous. The means or instrument to be used was not mentioned at all, as might be seen on referring to the minutes. The absence of snuffers, therefore, had nothing to do with the question.

The Secretary was not going to burn his fingers to please the gentleman who had just sat down.

The Chairman complained he had been interrupted. The last observation of the Secretary brought him at once to the proposition he was about to make just now. The last time he went to the play he had the misfortune to burst his gloves, a misfortune he now rejoiced in, for having that evening put on the same coat, he had them in his pocket, and he was thus enabled to offer the Secretary the use of the right hand one to protect his forefinger and thumb in the operation, which, he would no longer object to perform with such a guarantee.

The Secretary said that after the very handsome and liberal proposition of the Chairman he should not feel justified in any longer refusing compliance with the terms of the motion. He, however, noticed that the hole in the glove confided to him by the Chairman was only the stitching unsewed, and it could easily be mended. Under these circumstances he begged to state he had a pair of nail scissors in his pocket, and he would have the greatest pleasure in devoting them for this evening to furthering the interests of their society. (The Secretary accordingly immediately produced the instrument alluded to, and cleverly snuffed the candle.)

After a few complimentary remarks from several of the members, a vote of thanks was passed to Mr. Fuddle for his most valuable paper, the discussion on which was postponed to another evening.

Mr. Jones (of the firm of Brown, Jones, and Robinson) exhibited a card intended as a mount for stereographs.

Mr. Twaddle said he had ascertained by very careful measurement that the dimensions of the mount were precisely as stated upon the card.

After the customary vote of thanks to the Chairman, the meeting was formally adjourned.

Photographic Notes and Queries.

Blisters in Sensitizing Albumenized Paper.

Mr. Editor,—The troubles of a photographer are numberless, I am again obliged to call on Hercules to help my team forward. The present case is this, I sometime since purchased a quire of albumenized paper, warranted to be the *best:* how bad some might be I do not know; but I find each that I have used like the piece enclosed; when drying after sensitizing, it blisters as if it had the small pox, and on printing, the top of many of the blisters becomes stained as if the pimple had broken, and a virulent pus had exuded. Can you oblige me by telling me the cause? I applied to the party of whom I purchased the paper, sending specimen; and the reply was, that I had spilt some hypo over it, and used too much alkaline in toning: now the blisters and spots appear before being toned at all, and no hypo has had a chance of coming near it. This puts me in mind of the description of a crab given by a learned society as being a fish of a red colour and walking backwards; which was submitted to a famous naturalist, who said it was very exact except that the crab was not a fish, was not of a red colour, and did not walk backwards. I certainly feel vexed after paying a fair price, that I cannot use the article: it may in some way be my own fault, but I cannot imagine how that can be. Please to let me have your opinion on it, and you will greatly oblige. Will you also please to tell me how I can best contrive to dry several pieces of sensitized paper at once, without risk of the wet corner curling up and making a stain wherever it may touch the other part of the sheet. It takes so much time to sensitize and dry one piece at a time.—I am, dear sir, yours very truly, T. P. E.

[This difficulty is a new one to us and we publish the letter in order to learn, if possible, whether any of our readers have met with it. We are very familiar with blisters, which sometimes occur in the toning bath, but more frequently in the hypo, and which generally subside on drying. These it appears occur at an earlier stage and cause a stain of a bluish black or grey colour in the print which is forwarded for inspection. Is the silver bath highly alkaline, or acid? As to the curling up on drying all albumenized paper will do that; but if properly hung there should be no chance of stains. Suspend each piece by one corner, and attach to the other corner, where the drop collects, a piece of blotting paper. The paper will curl as it dries, but there can be no contact with any part wet with the silver solution. If you suspend by *two* corners this may happen.—Ed.]

Talk in the Studio.

Panoramic Photography.—The panoramic lens in the hands of Mr. Ross has been turned out a complete success. We have just received from Mr. Sutton an exquisite specimen consisting of a view of St. Brelade's Church and adjacent scenery, including an angle of upwards of 90° on the horizontal line, and 55° vertically. The picture is about 9 inches long, by 4½ deep, and is produced by a lens of only 5¼ inches focal length. The definition is throughout very fine, and is pictorially sufficient through every gradation, from the foreground to extreme distance. With the amount of subject included there is a fine picture, which would be comparatively worthless if it only contained one-third, or a little more, the amount usually given with a common view lens. The negative, which was taken on a tannin plate, is manifestly a very perfect one, soft, and vigorous, and giving a nicely tinted atmospheric sky. For a large class of subjects there can be no doubt the panoramic lens will be invaluable in its range of pictorial effect. We understand Mr. Ross has purchased the patent of the lens, and is now engaged in producing apparatus for stereoscopic sizes, and one to produce pictures about 30in. long, as well as intermediate sizes.

Instantaneous Photographs.—We have recently seen some very fine instantaneous pictures of Scottish scenery by Mr. Wilson of Aberdeen, which he had forwarded to Mr. Dallmeyer as specimens produced by the 6 in. by 5 in. triple achromatic lens. Amongst these were some fine views of Her Majesty's residence at Balmoral, mountain scenery, water-falls, sea pieces with shipping, &c. In one or two cases there were traces of slight under-exposure; but the wide angle, the exquisite definition, the well-chosen points of view, and above all, the exquisite natural clouds render these pictures perfect gems. The charm which a photograph receives from a tint in the sky, and a few delicate natural clouds, is most unspeakable, and worth any cost of effort or appliance to secure.

Photographic Identification.—The *Times*, relating the capture of a fraudulent bankrupt, named Ladislaus Kiss, by Haydon the detective officer, illustrates one of the uses of photography. The bankrupt has absconded with £40,000; he was traced through various parts of Italy by the officer, and finally ascertained to be in Turin. The officer did not know Kiss personally, but was possessed of the unerring guide, a photograph, from careful consultation of which he had become familiar with the man he wanted. The *Times* says "in a day or two Haydon met a well-dressed man walking in one of the principal streets. The practical utility of employing photography to assist the ends of justice was now proved in a most convincing manner. The photograph established the fact that the man coming down the street in a quiet unsuspecting manner was Kiss himself." Haydon left him a prisoner in the hands of the Venetian police.

Royal Photographs.—Mr. Lacy, of Ryde, Isle of Wight, was recently summoned by Her Majesty to Osborne, for the purpose of producing portraits of the Crown Prince and Princess of Prussia, the Princess Beatrice, the Prince William of Prussia, and the Princess Charlotte of Prussia, together with the various ladies and gentlemen of the suite, amongst whom were the Baroness von Dobeneck, Baroness Brühl, Count Furstenstein, the Countess of Desart, and the Honourable Victoria Stuart Wortley, Maid of Honour to the Queen.

Book Postage to France.—By a recent arrangement the advantages of the book post are established between this country and France. Photographs, patterns, commercial and legal documents, printed, engraved, or lithographed works bearing corrections or manual notes, manuscripts &c., provided there be nothing in the shape of a letter, may be conveyed under these provisions. Prepayment will be necessary.

Photography for Reproduction.—The *Athenæum*, referring to some of the pictures at Hampton Court, remarks:—"The cartoons of the Triumphs of Julius Cæsar, by Andrea Mantegna, have been protected by large sheets of glass, and are now seen to much greater advantage. The large chalk drawing, or cartoon, copied by Casanova from Raphael's Transfiguration, is in a miserably dark room, although one of the best and most valuable transcripts of the original picture, and of the same size. It certainly merits a more prominent position, and would, from the dulness of the surface, and clearness of execution, be a very good subject for photography. Copies multiplied by this process would render more service to students than any lithographs or line engravings now current; and we hope the authorities will take our second suggestion into consideration.

To Correspondents.

F. J.—We are glad you found the suggestion cure the evil. Your present difficulty will require a little experience in printing to enable you to avoid it always. All prints lose a little of the black tone on being placed in the hypo, but some papers more than others. Each different sample of paper may require different degrees of over printing in order to secure the right depth in the finished picture. To ascertain, examine the picture whilst toning, by transmitted instead of reflected light. If on looking through the print it looks brown, no matter how black on the surface, it will become brown in the hypo. Tone until you get a purple tint on looking through the picture. Test paper will show whether the hypo be acid or not; to prevent it becoming acid keep a piece of chalk in it.

James Thomas.—The use of the term grains in reference to fluids is rather a loose mode of expression, but cannot mislead us as it indicates the proportion. The exact strength of the ammonia or hypo solution to be applied after bichloride of mercury for darkening the deposit is not very important, but it should be extremely weak in order that its action may be under control. Either hypo or ammonia have a similar effect, producing brown or black, according to the strength of the solution and the time they are allowed to act. They are preferable to hydrosulphate of ammonia, as being quite as efficient and less offensive to use.

E. C. M. L.—We have heard the positive collodion of the first-mentioned form well spoken of. If your half gallon of collodion be not iodized, being a year and a half old, will not unfit it for being rendered sensitive by iodizing. If it have been iodized that time, and with a simple iodide, it has probably lost much of its sensitiveness; try the addition of a bromide to it. 2. The size of the camera should be proportioned to the power of the lens, and will make no difference in the rapidity. 3. In taking pictures with the film turn from the lens in order to produce non-reversed portraits, the ground glass should be adjusted to give a correct focus for the plate in that position. 4. In copying pictures the same size, or a little less, there is no necessity to reverse the lens. Either of the lenses named will serve for copying, but we cannot tell you which would be best without examining them.

Very Troublesome.—The only certain method of ascertaining the specific gravity of liquids is by means of the hydrometer or specific gravity bottle. The oil of vitriol of commerce is generally sufficiently strong for use in the manufacture of pyroxyline, and a trial, observing the conditions we have recently laid down, will best decide any modification in the proportions.

M. A. is thanked: his communication shall receive attention.

F. L. B.—You may use your silver bath weaker, and print the negative in strong sun-light. You will probably by this means succeed in getting a softer print. Your tones are too cold and inky.

H. J.—The term "Depth of Definition" was first suggested by ourselves in an article on "Depth of Focus," to meet the difficulty in applying the term depth to that which could not possibly possess depth. The perfection of focus could only exist in a mathematical plane, whilst sufficient definition ought to exist in every plane, and its use involves no contradiction of terms. We subsequently suggested the term to the gentleman referred to, who immediately perceived its suitability.

A Novice.—An ordinary quarter plate lens can scarcely be hoped to cover a standing figure for *carte de visite* portraits properly. Either a good half plate lens, or one made for the purpose, should be used. Regarding the question of selecting, we cannot advise you in these columns, but will write to you.

L. P.—Rolling improves prints very greatly, and by pressing the fibre of the paper firmly together, seem to give improved definition. Card portraits should never be sent out unrolled.

H.—We have mentioned the subject spoken of in your letter to Mr. Crookes, the editor of the *Chemical News*, who, we believe, undertakes professional analyses. He will communicate with you on the subject. In such a case as this, where important commercial interests are at stake, it is best to get a professional opinion at once, and not trust to an amateur analyses.

T. S. Swatridge, Yeovil, would esteem it a favour if any gentleman would kindly forward him per post, the address of Oscar Lawson, Artist Photographer.

R. A. C. asks, "Is it your opinion that when a collodion at 2d. per oz. which produces a moderately good portrait is mixed with a collodion at 6d. per ounce, which produces a good portrait, that the mixture will produce a *better* portrait than *either*." We must confess that we are a little puzzled with the idea of a collodion retailed at 2d. per ounce giving portraits at all. The mixture of two collodions often produces a better result than could be obtained from either alone; but that depends on their possessing opposite qualities, the one too soft and the other too intense, and would not be at all regulated by their respective prices.

A Continental Subscriber.—We do not remember at the present moment such a person as you describe. Your best plan will be to insert an advertisement in our columns, stating such particulars as you have given to us, and add the amount of capital which would be required.

W. W.—The old hypo bath is now abandoned by most good photographers. Some few still use it, and their prints may generally be detected by their yellow tint. By all means use the alkaline method. There is no harm in your trying the whole of them. The acetate of soda is producing good results in many hands.

James.—It is an excellent plan to have two samples of collodion, one very intense, and simply iodized: and another containing a bromide, and giving very soft pictures. You can then by mixing the two in different proportions from time to time, produce any result you may desire.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

⁂ Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 156.—*August* 30, 1861.

IRON NEGATIVES AND BRILLIANT PRINTS.

The use of salts of iron for development has within the last few years become very common, and among portraitists is now all but universal. Contemporaneously with the use of iron for development, the addition of a bromide to negative collodion has also become common. The advantages of an iron developer, and bromo-iodized collodion in giving clean and soft detailed negatives, with a short exposure, as compared with the hard, chalky, dense negatives so common under the pyro règime, have been unhesitatingly recognised. It is true that when the pyroxyline is just of the right quality, the ether very pure, the alcohol just in the right proportion, the collodion just iodized sufficiently long, and the bath in precisely the right condition, when all these conditions are combined, most exquisite negatives may be obtained with simply iodized collodion and pyrogallic acid development; but the delicate balance necessary is perpetually altering. The collodion that is perfect to-day is changed to-morrow, and still more so the next day, so that the amount of exposure under similar conditions of light must be perpetually varied. When the collodion is too newly iodized, it is sensitive but spotty, and it is very difficult to get clean pictures; when it has been long iodized it is insensitive, and it is next to impossible to get soft pictures. With the bromo-iodized collodion an average degree of sensitiveness may be maintained for months without sensible alteration, whilst clean pictures may be obtained within a few hours after iodizing. With iron development perfectly detailed pictures may be obtained with half the exposure necessary with pyrogallic acid, except when all the conditions suitable for the latter are present. It is not surprizing then that amongst portraitists generally, and amongst landscape photographers where extreme rapidity is necessary, the use of iron development and a bromo-iodized collodion should have come into extensive use.

But it rarely happens that an advantage is gained in one direction but at the cost of some evil in another direction. A new class of difficulties have sprung up as the attendant sprites of bromine and iron. Rapidity has been gained, cleanness has been secured, and the pictures are more generally soft. But they are often feeble and poor; they lack vigour and brilliancy, and they are especially difficult to manage under the alkaline gold toning system. The tendency of bromine is to give a thin grey superficial image without any density or opacity in the deposit, with veiling of the shadows. The tendency of iron development is just in the same direction. The consequence is, that unless some care be exercised, a thin grey veiled image is obtained, difficult to intensify, and not sufficiently repellant of light, however much it may be intensified. The consequence is, that meagre flat prints, without either rich blacks or pure whites, are not uncommon.

To avoid these evils, and succeed in producing brilliant as well as soft prints, where iron development is used, it is important to possess, in the first place, a correct idea of the kind of negative desirable, and in the next place a knowledge of the precautions necessary in producing it.

As regards the negative it is not necessary that it should be very intense, but it must be brilliant. With pyrogallic acid development a negative may be obtained, which by reflected light is quite invisible, the film presenting one universal drab surface. The same negative may, however, by transmitted light, may present a picture perfect in gradation, which in printing gives the most satisfactory results. With iron development such a negative would give a flat poor picture without relief, richness, or vigour. The intensity of the lights would not have increased in the same ratio as the deposit in the shadows, so that in printing the whites would begin to print through before the shadows had obtained sufficient depth. With pyrogallic acid development a negative which presents anything of a positive character, showing a well defined image by reflected light, especially if in places there be bare glass, will generally give a hard picture, with chalky lights. With iron development a negative may with propriety give some indication of the character of the image by reflected light; it must have no deposit on the deepest shadows, and may present in a few points merely bare glass.

An iron negative may be thin, delicate, and soft, and yet give brilliant prints, *but it must possess its proper scale of tones or gradations.* This is really the point of importance. To illustrate what we mean. Suppose a picture to possess twenty gradations of tone: to be perfectly produced in photography, the negative must consist of twenty gradations of thickness or opacity of deposit. A negative which commences with bare glass or entire transparency, allowing the uninterrupted passage of light for producing its deepest tones, and contains the various gradations up to twenty may not appear very dense even in its highest light, and may yet give a perfect and brilliant print. A negative, with a deposit over the deepest shadows, of an opacity equivalent to ten gradations, must possess in its highest light a deposit equivalent to thirty gradations of thickness or opacity, in order to give a good print; and if it only reach twenty-five gradations of deposit in its most opaque part, although it may appear to the eye considerably more dense than the first-named negative of twenty gradations, it will nevertheless yield much less brilliant prints: prints in fact whose scale of tones will back just five gradations, and which look meagre, poor, and comparatively worthless.

Let it be remembered then, as an axiom, that a good iron negative is generally a thin one, and that it must commence with bare glass for its lowest scale of tones; but that, as in a good picture the lowest scale of tones, or black, is very sparingly used, a good negative will present some, but very little bare glass, or points without any deposit whatever.

Having then a distinct conception of the result to be produced we proceed to consider the means necessary to this result. These consist in the preservation of proper conditions in the collodion, the silver bath, and the developer, and we shall consider them in this order.

Regarding the collodion a very common mistake prevails. Many photographers have an impression that to produce a negative by iron development a positive collodion is necessary, and they speak of the result as a "converted positive," or a "negative by the positive process." The negatives produced under such an impression are generally of such a character as to serve as a beacon and warning to all who have not yet tried the process. In the long-continued attempt to get vigour by a subsequent intensifying process, the shadows are veiled, and the half-tones are buried and destroyed by a coarse granular deposit. The prints are poor flat affairs, possessing neither pure whites, deep blacks, nor delicate half-tones.

A collodion suitable for iron negatives should give decidedly more intensity than is usually desirable for positives, or a tame flat picture which intensifies imperfectly will be the result. It should be made with pyroxyline obtained at a high temperature, somewhat organic in character, and dissolving freely at least six grains to the ounce of solvents without being at all thick or gelatinous. Sufficient pyroxyline is one important element in the production of a dense creamy film in the nitrate bath, and subsequent intensity in the negative. Such a collodion, when simply iodized, would in a very short time give hard, chalky pictures, but the addition of a bromide preserves sensitiveness and gives softness. The amount of bromide should be proportioned to the character of the pyroxyline. A pyroxyline, having a tendency to give great density, will easily bear half-a-grain, or sometimes more, of bromide to the ounce; but in many cases, for negative portrait collodion, one-third of a grain will be found to confer softness and cleanness, and preserve sensitiveness, without impairing intensity. The iodizers we have found best for the purpose have generally been a mixture of iodide of cadmium and the iodide of some alkaline base, either potassium. ammonium, or sodium. But whilst cadmium confers stability, it should by no means be used alone, for two important reasons: it is apt to confer glutinosity upon the collodion if it contain as much pyroxyline as we have recommended; and for some length of time after it is iodized, there is often a slight tendency to that foggy deposit in the shadows which is so fatal to the value of thin negatives.

To those who do not make their own collodion we would recommend a very simple expedient for generally possessing a stock in the desirable condition, Procure a stock from some maker well known to prepare a very dense collodion of the character so much in request some years ago. There are two or three makers known to prepare such a collodion. Sensitive and soft whilst newly iodized, but spotty; becoming in a few days very red, and giving chalky, intense lights, and masses of transparent glass for shadow. Have also a stock of positive collodion, giving a thin, clean, soft, detailed image. Mix these in various proproportions until the right one is found for giving clean, soft image with sufficient density; an intense, brilliant image with sufficient detail. As, from time to time the condition of the bath, the quality of the light, or the temperature changes, the proportions may be varied in order to get a little more sensitiveness, softness, or density, as the case may require. By adopting this plan almost any class of result may be had at will with very little trouble.

It sometimes happens that the collodion is working in some respects well. The right amount of intensity is present, and it is combined with sufficient detail. But is associated with a slight tendency to reduction of the shadows. This will most frequently happen when the collodion is new and newly iodized, especially if a large proportion of cadmium is present. The addition of an old coloured collodion will frequently remove this tendency; but if this cannot be conveniently done, or if the tendency to deposit be not removed without adding a proportion which would interfere with sensitiveness; then the addition of a few drops of tincture of iodine will frequently be found to answer the purpose; the amount should be proportioned to the state of the case, enough to make the collodion the colour of pale sherry will generally be sufficient. The addition of free iodine to collodion for positives, with a view to preserve clean shadows, is a practice of well-known value. In collodion for negatives its presence has generally been considered inimical to sensitiveness; but this will be found to be the case chiefly with pyrogallic acid development. Where iron is used, ond other things are in harmonious condition, its presence, in moderate proportions, will not be found to affect sensitiveness in any sensible degree. The use of about one drop of hydrobromic acid to an ounce of collodion, which is occasionally recommended in the positive process for the same purpose as free iodine, will be found to have a similar effect in iron negatives, without any advantage, however, that we know of, over tincture of iodine.

In some samples of collodion made with anhydrous ether and alcohol, it is difficult to obtain a dense creamy film; a thin opalescent effect, giving a feeble picture only being obtained, even by prolonged immersion in a strong nitrate bath. Where this effect is observed, and at the same time a disposition on the part of the film to repel the silver solution, it probably arises from the aqueous solution of silver penetrating the iodized film with difficulty. A few drops of distilled water to each ounce of collodion will at once open its pores sufficiently to allow the free permeation of the silver solution, and a dense creamy film, giving a brilliant image in place of the feeble picture before produced, may be at once obtained.

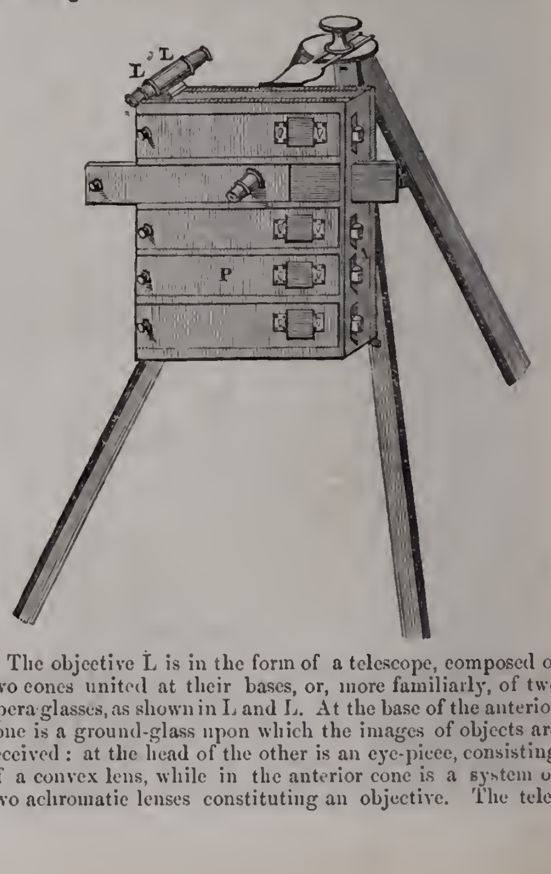
The addition of various kinds of organic matter, and other substances, either as accelerating agencies, or as giving increased intensity, is generally undesirable. We have tried various kinds of essential oils and hydrocarbons, various gums and resins, acids and acetates, hydrochloric acids and chlorides, &c. &c. &c. In many cases a slight advantage is gained for a short time, but always at the expense of subsequent loss, and we do not at all recommend the use of any of them. Good pyroxyline, pure ether and alcohol, in about equal proportions, or with an excess of the latter; pure iodides and bromides, in the proper proportions, are all that are needed in the collodion to give good iron negatives. The bath and developer must, of course, be in harmony; and these we shall consider next week.

THE POLICONOGRAPH.

INVENTED BY M. JULES DUBOSCQ.

M. Duboscq, who has already rendered many important services to photography, has recently invented an apparatus specially intended to enable an operator to obtain a large number of views during a journey; and to which, consequently, he has given the name of *The Travelling Policonograph.*

This apparatus is composed essentially of three parts:—the camera, the tripod, and slide: it is represented adjusted for taking views in the annexed woodcut.



The objective L is in the form of a telescope, composed of two cones united at their bases, or, more familiarly, of two opera-glasses, as shown in L and L. At the base of the anterior cone is a ground-glass upon which the images of objects are received: at the head of the other is an eye-piece, consisting of a convex lens, while in the anterior cone is a system of two achromatic lenses constituting an objective. The telescope, as shown in L, is placed on the tripod, and fixed by means of a screw.

The camera P is a large frame, at the bottom of which the sensitized collodion plate is placed, while in the dark room. The upper surface of this frame is complex in its arrangement. At A is seen a series of five double slides, the shutters of which move in opposite directions. Upon the upper shutter the anterior cone of the telescope is fixed: each row is divided into three parts by black, vertical screens, and the opposite motion of the shutters has the effect of bringing these three spaces opposite the telescope, and of proportionally uncovering the part of the collodioned plates corresponding with them. In this manner we can obtain three views in a row, and, consequently, fifteen views upon the entire plate.

The distance of the objective from the ground-glass exactly represents the thickness of the camera: if the objective is focussed upon the ground-glass, it will be so also upon the sensitized plate.

The frame is furnished with two screws upon its upper portion, in which the telescope is fixed by means of a bayonet-joint to obtain the focus. On the two fore feet of the tripod are two hooks which hold the frame during the operation: this mode of suspension is much more stable than that adopted in ordinary apparatus.

The operator proceeds in the following manner:—With the complete telescope in his hand, he selects the landscape or other object he wishes to photograph; then fixing it upon the frame placed on the tripod, he focusses the object on the ground-glass. Then separating the objective and placing it on the first row, the frame already resting on the legs of the tripod, he works the shutters, proceeding in the ordinary manner to take as many negatives as may be desired, without any other labour than that of working the slides of which he moves the notches marked 1, 2, 3, &c., in succession, and the catches which hold them during the exposure. The plate with its fifteen negatives may remain in the frame until it is convenient to develop it. On regaining the operating room the plate can be developed and fixed, and positives printed from it in the usual manner, or the negatives may be enlarged, if desired. An amateur who wishes to avoid as much trouble as possible, has only to provide himself with a sensitized plate, which, after exposure, he can send to a professional photographer to be developed, fixed, and printed. The complete apparatus is extremely portable; the frame can be placed in a carpet bag, the camera in the pocket, while the tripod serves as a walking stick.

Thus a very interesting question has been solved in a very simple way by M. Duboscq. Artists as well as amateurs will find it to their interest to photograph landscapes and architecture, and thus obtain exact models which they can afterwards convert, at their leisure, into artistic pictures, in their studios, and it is certain that painters would frequently have resource to photographs if its processes were sufficiently simplified.

COLLODION-PHOTOGENE FOR POSITIVES AND NEGATIVES.

BY M. MC. A. GAUDIN.

Having, in my researches upon washed collodion plates, become satisfied that the nature of the developing agent, and the mode of developing, have the greatest influence upon the intensity of the pictures, I have resumed the preparation of a *photogene*, and I have the pleasure of announcing to my readers that I have succeeded in preparing a photogene which has yielded me positives as white as snow, and printing negatives of extraordinary purity. I cannot now state exactly how it is composed, for its preparation was of a very complex nature; but the fact is quite certain, and, as I have frequently stated, the photogene will soon replace collodion sensitized with nitrate of silver.

At present, I operate in the following manner:—I pour upon the plate some photogene, which is of a greenish yellow in the mass, and of a very pure opaline colour on the plate: thus prepared, the plate is at once ready for use, but in all probability it will retain its sensibility for an indefinite period, for the photogene never dries.

After exposure in the camera, the plate is washed in the acidulated water intended for sensitized plates; when it ceases to appear *greasy*, a pyrogallic developing solution is poured on; and when this latter has become thoroughly imbibed, nitrate of silver, of the strength of 3 per cent. is added, which causes a splendid picture to make its appearance.

At present this photogene requires an exposure double in length to that of ordinary sensitized collodion; but as it is found to be fifty times slower in obtaining positives on paper than certain impenetrable photogenes I had prepared previously, there is nothing to fear on this score, and I have not the least doubt of being able to prepare photogenes which will leave nothing to be desired as regards sensibility.

I have endeavoured to ascertain whether the photogene retains its sensitiveness for any length of time. After coating a glass plate with it I placed it in my little apparatus, the diaphragm of which consists of a piece of card-board pierced with a pin-hole, with a diaphragm of 7 millimètres; this apparatus gave me a negative upon collodion sensitized in the usual manner, after an exposure of 10 seconds, with a simple achromatic lens. My photogene was about twice as slow, it required 20 seconds with this latter diaphragm, and fifty times as long with the pin-hole aperture; that is, 1000 seconds, or a good quarter of an hour; but I left it two hours in position, and upon proceeding to develop, I obtained only a fraction of a sky with the distance, as a very weak positive.

I do not conclude from this failure that my photogene will not retain its sensibility a notable length of time, because my apparatus was in an extreme condition; it was exposed to full sunshine at the back, and when I examined the plate before development I saw it was covered with liquid globules, having evidently undergone a sort of cooking, which doubtless destroyed its sensibility.

Immediately afterwards, I took a negative with the same photogene, and with the aperture of 7 millimètres; this negative I found perfect in every respect, and upon comparing its sky with other skies upon negatives obtained by the ordinary process, the sky of the photogene appeared to me twice as intense.

In leaving out of consideration for the present the question of permanence of sensitiveness, which I am induced to attribute to the photogene, a question I shall immediately solve, it remains established that the photogene can be substituted for collodion sensitized with nitrate of silver, and that even washed collodion itself already appears to have become an old story.

Yesterday I again experienced considerable difficulty in preparing a fresh supply of photogene that would work well; but I have thought of a process which will enable me to prepare it with mathematical precision, as I shall be guided in the proportions by a well-marked change in its colour; and I now perceive that I shall be able to prepare a photogene with albumen, which was impracticable by my former method.

Thus we shall soon have photogenes of collodion, gelatine, and albumen, and then photography will be greatly simplified and rendered much more attractive.

By employing the inexhaustible resources of chemistry, we shall arrive at obtaining preparations possessing perfect porosity, and as I have already obtained impenetrable collodion photogens upon glass, but more sensitive upon paper than the most rapid collodion, we cannot doubt that a brilliant future is reserved to this improvement.

In this manner everything becomes possible, and I have no doubt of the preparation of an extra-sensitive photogene, which will serve an indefinite time after being poured on the plate; for I perceive very clearly that the means exist of rendering the photogenic preparation rigorously insensible to every influence, except actinic power, at the ordinary temperature.—*La Lumière.*

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Hydrocyanic Acid.—Although this acid is only very rarely used in photography, and is too deadly a poison to render it advisable for any unskilful person to dabble in its preparation, yet this series of acids would be incomplete were we to omit all mention of it. Hydrocyanic, or prussic acid, is always prepared by the reaction of sulphuric acid upon ferrocyanide of potassium. 10 parts by weight of the latter are mixed with 7 parts of oil of vitriol which has been previously diluted with thirty or forty times its bulk of water. The ferrocyanide should be well powdered and the mixture placed in a glass retort and submitted to careful distillation. The greater part of the hydrocyanic acid goes over in the beginning of the distillation at a temperature somewhat above 212° F. A good condensing apparatus is therefore necessary, otherwise the hydrocyanic acid which passes over first, since its boiling point in this concentrated form is not above 81° F., will, for the most part, escape in vapour along with the air in the apparatus. To avoid this loss as well as the great danger to the operator's health which its inhalation would cause it is advisable to have water in the receiver into which the concentrated acid can condense. The retort must be so arranged as to prevent any of the contents from spirting over, and the receiver should be surrounded with ice. As soon as two-thirds of the liquid have come over, the distillation may be stopped. The liquid in the receiver should be transparent and colourless, it should have but a very transient and feeble action on litmus. It has a very powerful odour somewhat resembling oil of bitter almonds, but more stifling; its taste is bitter and pungent; it destroys life more quickly than any other narcotic poison, a fraction of a drop of the strong acid being almost instantly fatal, and even its vapour when inhaled producing coughing, giddiness, and headache. The acid is very prone to decompose, producing cyanide of ammonium, formic acid, and a variety of brown substances.

The acid which is distilled over in the process given above will be of unknown strength, and since it is very important that the exact amount of anhydrous acid which it contains should be known, its strength should be ascertained. The best plan for estimating this is the process known as Liebig's. The hydrocyanic acid is mixed with a solution of caustic potash until a strong alkaline reaction is produced, and then with a graduated solution of nitrate of silver until the liquid begins to show signs of turbidity. 1 atom or 108 parts by weight of silver used will correspond exactly to 2 atoms or 54 parts, by weight, of anhydrous hydrocyanic acid.

Hydrocyanic acid is not liable to intentional adulteration. It may, however, contain several impurities arising from the mode of manufacture adopted. These may be sulphuric, hydrochloric, nitric, tartaric, or other of the stronger acids; sulphuretted hydrogen, ammonia, oxide of lead, cyanide of mercury, formic acid, and hydrosulphocyanic acid. The *strong acids* may easily be detected by the fact that blue litmus paper dipped into the liquid is turned instantly blue, and remains so after a day's exposure to the air. *Sulphuric acid* may also be shown by the turbidity produced in the liquid by a solution of chloride of barium in the presence of a drop of nitric acid. *Hydrochloric acid* may be detected by adding excess of ammonia and evaporating the solution to dryness on the water bath, if pure there should be no residue. The residue, if any, dissolved in water, and mixed with nitrate of silver and nitric acid, will give the well-known white precipitate of chloride if this contamination is present. *Sulphuretted hydrogen* may be known by the brown precipitate which is given by it to a solution of cyanide of mercury. *Ammonia* causes the acid soon to turn brown, it may be recognised by the white cloud which it forms with hydrochloric acid when a glass rod moistened with this acid is brought near the liquid to which an excess of potash has been added. *Oxide of lead* is easily known by the dark colouration given to it with sulphuretted hydrogen. *Cyanide of mercury* will be left behind when the acid is evaporated to dryness at a gentle heat. Formic acid is not an uncommon impurity, as it is produced by a slight excess of mineral acid in the process of manufacture; it may be recognised by dissolving a little mercuric oxide or cyanide of mercury in the liquid, and then heating to the boiling point; formic acid will cause the reduction of the mercury to the metallic state, which will precipitate in minute grey globules. *Hydrosulphocyanic acid* is at once known by the deep red colour produced in liquids containing it upon the addition of a drop of perchloride of iron. If a little of the hydrocyanic acid leaves any residue upon evaporation to dryness over the water bath, it may consist of phosphoric or sulphuric acid, sulphate of potash, prussian blue, bitartrate of potash, oxide of lead or cyanide of mercury.

The presence of hydrocyanic acid in any liquid is detected in a very simple manner. The suspected liquid is placed in a watch-glass, this is covered with another which is moistened with a drop of sulphide of ammonium. After a few moments the upper watch-glass is gently heated till the sulphide of ammonium is dry, and the dried residue is treated with perchloride of iron. A blood-red stain is produced if hydrocyanic acid has been present in the liquid.

Hydrocyanic acid being such a deadly poison, it may not be inappropriate to devote a few lines to its physiological action, and the proper remedies to be taken in case of poisoning by its means. The ordinary prussic acid met with in shops is a mixture of anhydrous acid with water, the strength varying from two per cent.—that of the London Pharmacœpia, and Scheele's acid which contains five per cent. Even these dilute forms are very fatal in their effects, inhalation of the vapour of Scheele's acid having on more than one occasion proved almost fatal. Taken in the liquid form, as small a dose as twenty drops of Scheele's acid is considered to be sufficient to destroy life, the symptoms following one another with alarming rapidity, commencing sometimes even before the act of swallowing is accomplished, and death ensuing in from a few minutes to a few hours. The symptoms are perfect insensibility, the eyes fixed, prominent, and glistening, the pupils dilated and unaffected by light, the limbs flaccid, frothing at the mouth, the skin cold, and covered with a clammy perspiration; there is a convulsive respiration at long intervals, and the patient appears dead in the intermediate time; the pulse is imperceptible. The respiration (when the patient is not very far gone) is slow, deep, gasping, and sometimes heaving, sobbing, or convulsive. It must not be supposed that the poisoning action of this acid is only liable to take place when the acid itself has been taken. In many photographic operations, especially now that cyanide of potassium is coming into vogue again as a fixing agent, there is quite enough vapour given off from the solutions of this salt to produce alarming effects. Indeed we have known an instance where an operator who had been for some time experimenting over a dish of cyanide of potassium solution was suddenly seized with unmistakable symptoms of poisoning. He suddenly felt a pain in the back of his head, this was quickly followed be noises in the ear, giddiness, difficult respiration, and ultimately he fell down unconscious. In manufactories where electro-plating or gilding is carried on, cyanide of potassium being largely used as a solvent for the metals, it is not at all an uncommon thing for the workmen to be affected by slight symptoms of poisoning, since a solution of cyanide of potassium is always evolving prussic acid into the atmosphere.

The method of treatment in cases of poisoning by prussic acid should be adopted without a moment's delay. The nearest medical man should be instantly sent for, if a messenger can be spared, but in most cases he arrives too late. Death by prussic acid is like death by lightning—the person in general either dies speedily or recovers altogether, death taking place as early as the second minute or as late as the fiftieth; those who survive an hour having a good chance of recovery.

The first thing to be done is to deluge the patient with plenty of cold water dashed violently over him, a stream being allowed to flow down the spine and back of the neck. The vapour of ammonia should also be cautiously applied to the nostrils, and stimulating liniments by friction to the chest and abdomen. Internal remedies appear to be of no service, unless taken within a second or two of the poison. The blood is speedily poisoned, and no chemical antidote can reach this liquid to counteract the effects of the poison. If the power of swallowing remains an emetic may be given, and a mixture of sulphate of iron solution and carbonate of soda, but these are seldom of use. Plenty of cold water and smelling ammonia seem to be the only effectual remedies; lose no time in applying these and send for a medical man.

SOME NOTES ON POSITIVE PRINTING.

BY SAMUEL FRY.

As I suppose myself to be addressing readers who have already acquired some knowledge of photography, I avoid entering into those minute details which are indispensable where the beginner is concerned. I do not propose to communicate anything especially novel, but merely to mention a few of the details of my own practice, which will be found useful in the hands of amateurs and others. Probably few amateurs albumenize their own paper, for, as a rule, they cannot obtain extreme smoothness of gloss, and evenness of surface, which is found in paper albumenized by those who do it commercially. I am not myself an admirer of this extreme glaze, but beyond a doubt it gives wonderful detail and definition, and imparts a finished look to a picture, which is admired by many.

I believe it is not, as has been suggested in many cases, produced by very different materials to those commonly supposed to be employed for the purpose, and which, if not deleterious to the print, are at all events of doubtful utility.

Albumenizing.—For the information of those who incline to try their hands at albumenizing, I will give the recipe I employ with much success:—

White of egg	10 ounces
Chloride of sodium	2 drachms

Mix the salt before adding with just sufficient water to dissolve it. Beat up the mixture until the whole is converted into paste, and set aside to settle. When it is to be used, a room should be over-heated to 70° Fahrenheit, and with a good red fire or stove burning. This room should be swept out and dusted an hour before the albumen is poured out, and arrangements made to prevent persons coming in and out during the process, as cold draughts of air cause markings on the sheet by causing the flow of albumen in lines.

Filter the albumen through muslin into a glass dish with wooden sides, and commence by drawing a strip of cardboard over the surface to take off dust or scum arising from the bottom of the dish, and other causes; and having chosen the smoothest side of the paper, float it on the surface by laying the middle down first, and by the ends forcing out air-bubbles. Allow it to float one minute, then remove it, and suspend to dry by means of American clips attached to a cord stretched across the room. Where some of the surface albumen has run down, move the sheet to the front of the fire, and dry it up very rapidly, by this means a very high gloss can be obtained. Do not iron it out when dry, but place it under a board, or in a screw press to flatten it down. I do not use ammonia, acetic acid, or anything else mixed with the albumen, except the water and salt named. With some samples of paper it is very difficult to avoid streaks; and in such case I allow the albumen to stand a few days to become more limpid.

Sensitizing.—I invariably employ, as I have said, for sensitizing and albumenizing paper, a bath made of a stout piece of plate glass, with wooden edges varnished with shellac inside. A method of making them was recently given in the PHOTOGRAPHIC NEWS,* which is almost identical with my own. A much less quantity of solution is required from the perfect flatness of the dish, than for any other kind. I may, perhaps, appropriately mention here that it will be found of very great advantage to mix the sensitizing solution with common or river water instead of distilled; by this simple means may be obviated one of the commonest annoyances in a small way, to which photographers are subject, I allude to the great discolouration of the sensitizing bath after use. When the mixture is first made with common water a cloudy milky looking deposit is seen which gradually settles to the bottom of the bottle, but must on no account be filtered out, as it is this carbonate and chloride of silver which decolourizes the bath, or rather prevents any colour from arising, even after very extensive use of the bath solution. My method is thus, take say—

Crys. Nit. Sil.	8 drachms
Common water	8 ounces.

I place it in a rather tall bottle, agitating until dissolved, then put aside until next day, when it will be found quite clear. The solution being filtered out for use leaves the sediment at the bottom of the bottle; with half-an-ounce or so of this liquid, and after having sensitized the required quantity of paper, return it to the bottle and shake well. My own bath of half-a-gallon has been in constant use for months, with fresh added, and is as clear as spring water. I look upon it as being of primary importance to keep up the original strength of the bath by the addition of fresh crystals occasionally, as, when the silver is reduced to any considerable extent, it is liable or likely to produce three great evils. 1. The resulting proofs are poor and flat when finished. 2. The albumen is dissolved from the surface of the paper in consequence of the strength of silver being insufficient to produce coagulation before the water dissolves it. 3. Mealy brown spots are produced on the paper from the solutions acting unequally. I therefore argue that it is false economy to have a weak printing bath; the now well-known hydrometer offers a perfect security against allowing the bath to become too weak; every photographer should test his bath with it before sensitizing paper, and thus ensure brilliance and vigour in his tones.

Much has been written of late of the advantages of certain specified periods of time for keeping albumenized paper on the silver bath; my own experience leads me to think that in winter or cool weather, say nine months out of the twelve, it should never float less than from three to five minutes, but I have seldom found that ten did any harm, the prints on either paper being indistinguishable from one another; but I do think that injury may result from any further continuance of the operation, and perhaps a safe medium may be from five to seven minutes. *Saxe* paper is frequently absorbent, and will generally require a shorter time than *Rive* paper. Paper dried by the fire after floating rapidly discolours, but if used immediately appears to give increased brilliance and force to prints, probably from the surface becoming more thoroughly dry and ivory-like than is often the case when it is simply hung up to dry in the yellow-room. I recommend it, for ordinary use, to be sensitized in large sheets, suspended to dry in a yellow or dark warm room (carefully catching every drop that falls from it in drying), and when so nearly dry as to begin to curl at the corners, roll it up on an oak or mahogany stick the size and shape of a ruler; when all the sheets are on, one over the other, unless

* See "Amateur Mechanic," p. 261, vol. iii.

the paper is to be used at once, place the whole in a box, or what is better, a long glass bottle, having the bottoms covered thick with common salt, and with a thickness of paper to keep the prepared roll from touching. The deliquescent nature of the salt absorbs from the surrounding atmosphere a large per centage of its moisture, and by this simple means albumenized paper will retain its sensitiveness and pure white colour for three or four weeks, thus saving the amateur, whose time is limited, a deal of loss; independently of which it is far more economical to prepare a quantity of paper at once than to be continually pouring the solution in and out of the bottle.

I have long employed the above principle in my own establishment, and have every reason to be satisfied with its operation.

The less sensitized paper is exposed to the action of even weak daylight the better, for the clearness of the white and half-tones is very materially impaired by that yellowish-brown decomposition of the prepared surface, which arises sometimes in darkness from the spontaneous continuance of an action once set up in daylight. It is much better, when it can be done, never to allow the paper to be out of the yellow room until it is in the point for printing.

Should the printing frames, with screws to produce the pressure, be selected, care must be taken to apply the same force at each corner, and not to put a small negative in a large frame, as the probabilities are that the centre will have no pressure, from the screws being outside the edge of the negative. Again, if frames with springs are used, it requires care, from time to time, to see that the springs do not become too weak, and, therefore, inefficient for pressure.

Never print a picture without a good padding over the paper, or some substitute, as want of sharpness in some part of the picture is sure to be found from the neglect thereof.

Before commencing to print some kinds of negatives, which from defects, or other causes, require more exposure to light in some parts than others, the operator should make certain masks, or blinds, to be used in shading portions of the picture whilst others are going on. These are of simple construction, and are thus made:—The first, and simplest mask, consists of a square piece of stout cardboard the size of the pressure frame, to one or more edges of which is attached cotton wool by means of gum. This, when dry, is drawn out by the point of a pin, or a common comb, until it presents the appearance of a white fringe, projecting an inch from the edges. By judicious arrangement in masking the parts required, whether in the sky, the background, or other portion of the negative requiring less light, most charming effects are produced, and defects, at times, converted into improvements. Again, by placing here and there, on the outside of the pressure frame, at certain stages of the printing, a piece of wool to retard dark, sombre shadows, the resulting prints may be much improved if needful. The following description of mask will also give very fine results under certain circumstances:—Take a piece of cardboard, larger than the frame, and make an oval hole of any convenient size. If a set of 6 cards be made, with holes from $\frac{1}{4}$ up to $1\frac{1}{2}$ inch in the centre, it would be well, and gum round these apertures cotton wool, as before described. The use of these masks is seen at a glance; any obstinate fogged piece of negative, that ought to give us depth in the joint, may, by having this mask placed over it, moving the card about occasionally, be kept exposed to light, whilst the rest is obscured.

The system of masking, or "dodging" pictures, is one that in my opinion should only be attempted for the improvement of imperfect negatives, or those, which from accidental causes are defective as photographs, but exhibit artistic qualities, or pictorial beauties, which render their perpetuation desirable.

Under very favourable circumstances negatives may be now obtained, which contain within one plate every variety of cloud, atmosphere, animal life, and moving objects, rendering composition photography comparatively unnecessary; but it may well happen sometimes that the want of a sky, the presence of a stain, &c., may mar an otherwise good result; under these and similar circumstances alone, are these maskings permissible.

In every case the shading, &c., is to be conducted at the earliest stages of the printing, in order that the subsequent printing of the general body of its picture may obliterate any slight shade or hard line at the edges of the parts masked, as a little general exposure of the whole of the picture (in the printing-frame, and under the negative, of course), will tone down, or soften and blend edges, which in the masking process have become a little too much defined.

Whilst on the subject of paper printing, I may be allowed to advert to the extreme importance of avoiding all contact with the surface of the paper as much as possible. Warm or damp fingers touching albumenized paper on the prepared side, whether sensitized or not, are almost certain to cause marks which cannot be removed by subsequent treatment, and of course if the hands which caused these defects have been employed in other chemical operations, more particularly in fixing prints involving the use of hyposulphite of soda, the danger is greatly aggravated of spoiling a considerable quantity of paper.

In this matter probably nothing is a more certain preventive of conducting toning and sensitizing together by one process, than for the operator to be able to trace, on any particular occasion, the loss of valuable time and prints to this cause; the inclination is so natural, and the practice so common of endeavouring to economise time by those whose opportunities for photography are short and rare, that it cannot be a matter of surprise that the thing should often be attempted, and the blemishes attributed to other causes.

The subject of toning and fixing will require some separate notes on a subsequent occasion.

PHOTO-SCULPTURE.—A NOVEL PROCESS.

The following letter and editorial comments we find in the *American Journal of Photography*:—

Sir,—Having noticed in the *Scientific American*, of July 6, 1861, an article copied from the Photographic News, claiming that photographs can be taken in "Relief." I take the liberty of communicating to you a process by which, some eighteen months since, I took similar pictures; not with any degree of perfection, but of such a nature as satisfied me that the principle would make copies of any object of one colour in basso-relievo, correctly representing the original, in which copies or shells, any number of casts could be taken in plaster or other cold material, for similar purposes.

The process by which I made the representations spoken of was as follows:—

On a very thin sheet of gutta-percha, fastened on a frame by the four sides, I spread a coating of gum arabic mixed with bichromate of potash. When dry I exposed it to the light under an ordinary portrait negative, after which I dissolved away the soluble gum and dried it.

Thus far I copied nearly after the "carbon printing" process.

This sheet was now part elastic and part non-elastic. I next levelled the frame containing the picture with the printed side down, and poured warm water on it, which caused the gutta-percha to stretch where it was not covered by the gum, and allowed the high-lights to protrude and form "basso-relievo." Thus far everything worked to my satisfaction and expectation. I then allowed it to cool, when on turning it over, I discovered that the shirt bosom protruded far beyond the coat, making an unnatural representation.

I had not the time or material then to continue my experiments, but enough was gleaned from them to satisfy me that from objects of one colour, such as statuary, &c. (backed with practice), good copies could be made. Other gums than the one named might work better.

Having heard doubts expressed as to the plausibility of the process spoken of by the Photographic News, I have given you the result of my experiments as being the probable mode employed by Mr. Willeme.

My experiments and description are, of course, incomplete from the short time that I could spare upon them, but I have gone far enough to convince me that the principle of an elastic and a non-elastic gum is correct. Some of our enterprising Americans who have more time to spare can no doubt bring it to perfection. T. Cummings.

Lancaster, Pa., July 16.

[The above process is not at all like Willeme's; in our opinion it is far more ingenious, novel, and perhaps useful. Mr. Cummings' is the genuine photo-nature sculpture; Willeme's requires more of the handiwork of the human artist.

Willeme's process is briefly this: he sets up his model (a piece of satuary, for example), and makes a series of photographs of it all around it, and from the camera stations all in the same horizontal plane. These views will be profiles, *silhouettes*, or sections of the model. The sections, properly mounted on cardboard or metal and trimmed, are now set up and fastened together, so that the common line or axis shall coincide, and so that the several sections shall have their other proper relations to each other, and the work begins to assume the solid form; it is only necessary that the spaces between the sections be filled with plaster or wax, and the surface be smoothed and worked up by the artist.

The whole subject is interesting and suggestive. There is a fine field here opened for speculations and experimentations. We earnestly hope that Mr. Cummings will not abandon his brilliant idea.

It will be observed that Mr. Cummings' process will give form only to light and shade of the model, and that in no case will this form be the same as that of the model; a face, for example, will be wonderfully prominent on the side which is most illuminated. We shall thus have a new art; what shall we call it? Actino-light and shade-sculpture?—Ed.]

THE VALUE OF PHOTOGRAPHY.

The wisdom of the world, like its own physical phenomena, has its cycles; and civilization, like the pendulum, swings across an arc with slow but certain motion. The life of a nation has been compared to the tidal currents of the ocean; and habits, manners, customs, and fashions most surely ebb and flow. Thus, though the stream of modern civilization moves ever forward, it needs but little fancifulness to discover an occasional point in which we, nineteenth century folk, have reproduced the habits of our forefathers; generally, we must say, greatly improved upon and refined. Perhaps there is nothing in which this tendency is more noticeable than the revival of the pictorial instruction of olden days, which has been brought about by the introduction of photography; for that "pictures are the books of the unlearned" is a dictum quite as true to-day as it was when uttered by the fathers of the church—those fostering parents of education—fifteen centuries ago. But it is not now the ignorant alone who learn useful lessons from the photographer's art; on the contrary, our highest intellects and keenest eyes call in its aid to their assistance in the discovery and registration of some of the most magnificent as well as most minute facts of physical science. Without this magic artist at command, the astronomer, the meteorologist, and the chemist, together with many other investigators, would be deprived of one among the most powerful of scientific divining rods. How would it have fared, for instance, with our wise men this last summer, in Spain, without the camera and the sensitive plate? A hundred telescopes might be levelled at the lessening solar disc, and a hundred trained observers note with astonishing accuracy every visible phenomenon of eclipse; but each eye is more or less fallible, and looks only for a few seconds on new and startling appearances. The lens and the collodion, however, are observing too; the fleeting nature of the picture is as nothing to the obedient chemicals, and while human eyesight, and human memory, at their best, can do little more than carry away a faint and confused impression of the sight, *they* will take and retain an exact and lasting image of the strange and important appearances which accompany the event.

It is impossible to avoid comment upon the extraordinary development which marks the history of this art, and the enormous range over which its operations extend. It is difficult, in passing along the Strand or Regent Street, and noting the number and importance of the shops devoted to the sale of photographs, to realize the fact that all these results have sprung from labours so recent as those of Daguerre, Archer, and Mr. W. H. Fox Talbot. Twenty years ago the daguerreotype was an expensive means of getting a bad likeness; and now, for an absurdly small sum, we may become familiar not only with every famous locality in the world, but also with almost every man of note in Europe. The ubiquity of the photographer is something wonderful. All of us have seen the Alps, and know Chamounix and the Mer de Glace by heart, though we have never braved the horrors of the channel. The pyramids of Egypt would fail to astonish the most ingenuous of British schoolboys. We have crossed the Andes, ascended Teneriffe, entered Japan, "done" Niagara and the Thousand Isles, drank delight of battle with our peers (at shop windows), sat at the councils of the mighty, grown familiar with kings, emperors, and queens, prima donnas, pets of the ballet, and "well-graced actors." Ghosts have we seen and have not trembled; stood before royalty and have not uncovered; and looked, in short, through a three-inch lens at every single pomp and vanity of this wicked but beautiful world. —*Once a Week.*

Photographic Tourist.

MY FIRST PHOTOGRAPHIC TOUR—*Continued.*

Out in the morning early. The rising sun saluted us as strangers rarely visible to him and the hour, as we, inhaling the fresh enjoyable air, and discoursing hopefully and cheerfully of our future, soon found ourselves at the railway station one good hour before the time of starting.

We were not alone in our foolish eagerness to get away. A poor, little, hard-handed servant wench, who had toiled in some dull kitchen—kitchens are seldom anything but dull—for five long years without a holiday, was about to visit her friends and relatives at Norwich, for "a whole month, mum, a whole month," as she, bursting with the gladness and importance of the fact, exultingly told my wife; adding that she had already been at the station "a whole hour," and almost thinking, perhaps, that her haste decreased the time which separated her from those at home. And there she was, full of glowing anticipations, smiling at every thing, with eyes full of pleasure, making confidants of all who came near her, and evidently considering such glorious news as she was full of far too precious to be selfishly hoarded. Moving restlessly to and fro in a flutter of joy and impatience; now asking when she could get her ticket, or where she was to pay, or what time the train reached Norwich; and every now and then bursting forth to some new confidant with "*a whole month, mum, a whole month!*"

In due time the tickets were got, the luggage seen to, and ourselves esconced in some comfortless cages ignominiously labelled "for the working classes," where we were speedily jammed into the smallest possible space, with our knees fitted neatly between those of the opposite travellers. Thus, with puffing and clanging, and banging and rattling, away went we, our only source of amusement in the close hot den being the incessant talking of a tall dame on the one side, the melodious cries of some unhappy infants on the other, and the coarse chaffing of a drunken farmer in our front, so that we were not grieved when the train stopped, the shout of "m'fard" greeted our ears, and the name, Chelmsford, greeted our eyes.

Descending from the station to the earth we passed between two rows of little wooden houses, and some modern brick buildings of the true cockney cut, and so on to the market-place, with its dusty statue of Justice Tyndall, poring over a black no-lettered volume, and doing treble duty by also supplying water and supporting four small lamps.

Proceeding to hunt apartments we went through the High-street, no very great distance, but which, nevertheless, with one or two streets on either side constituted the *county* town of Chelmsford. In the course of our rambles we discovered the Shire Hall, of which the inhabitants are proud, the Literary Institution, which the inhabitants, of course, neglect, the Religious Tract Depository, which the inhabitants support, and a vast array of beer-shops and inns, which are more flourishing than all the rest put together.

Seeking some economical refreshments—for a guinea isn't much to start, in a strange town in a new business, with, is it?—we made our way out of the town to a little road-side public-house, and sat down in its parlor, on an oaken seat, which was also a locker, with our feet on the sanded floor, and some home-made bread and Dutch cheese (*without plates*), and some beer in an earthern jug, on the white, well-scrubbed deal table before us. It wasn't a luxurious meal, certainly; but what of that, we enjoyed it. Afterwards we engaged a bed here, and a very snug, snowy, little nest it was, with quaint, old windows containing small diamond panes of green glass cased in lead, also having a very large share of timber, and curtained with clean check curtains; the whitewashed walls were spotless, and the flooring nearly as white, and there were white curtains, and a white counterpane, and such neatness and cleanliness there apparent as I believe one never meets with anywhere out of England. Here, soundly and sweetly, after the fatigues of the day, we fell asleep, having first secured some cheap apartments, of which we could take possession in a day or two, for our first venture as travelling photographers.

A long country ramble occupied the next day, our food still being bread and cheese, and our hearty enjoyment of such humble fare a thing to be envied by many holders of a pampered appetite, or never-hungry lot. So pray don't waste pity on us, for we didn't deserve it. Our dinner that day, I remember—oh! so well—was taken in the shadow of a fine old tree which stood upon the sunny slope of a hill; a splendid prospect was before us, and a full band of feathered minstrels were making music for us the while. I have sat down to a table groaning with the richest luxuries since then, but never enjoyed a meal so well as I did that. There was not a soul near, the magic of the glorious sun hung glistening diamonds on the leaves, burnished the gleaming blades of grass, gilded the rough old bole of the tree, bathed the distance in a radiant flood of glowing light, and seemed to defy us to be ought but gay, and hopeful, and care-defying, and merry; aye, and vocal, for after dinner we lay on the grass and sang to one another, sang as the birds sing, out of sheer joy and our instructive sense of freedom.

You are mocking us, perhaps; you think us idle, thoughtless, and careless: think, may be, that we ought to have been sitting tearfully, hand locked in hand, with visages drawn out to their longest, contemplating our sad position with mournful earnestness and making ourselves supremely miserable. We were not so soft, my good friend, the troubles would come if they were to come, but as to going a long way to look for and meet them, that was not set down in our list of intentions, and we didn't do it. They came, as, alas! you will see, but we fought none the worse with them for the strength we obtained from encouraged hopefulness.

To shorten my story. We got into our apartments, and when we had recompensed the man with his truck for conveying our luggage from the station, and paid the first week's rent in advance, we possessed in cash just *one shilling*.

I had prepared a case of specimens with the aid of my instructor in town, and now proceeded to unpack the same, but when the lid of the packing case was removed—Oh! horror!—there lay the case with its glass shivered to pieces!

With a muttered d——n, I looked from this unfortunate case up to my wife, whose eyes were full of tears as she came to my side, and looking without a word up into my face with her loving mournful smile, kissed me. I pressed my lips passionately to her dear little face, and then set to work to remedy the evil by spending my last shilling with a glazier, who cut the remnants into square pieces, which with gum and paper and metal "mats" I contrived to convert into a number of small cases for the reception of our specimens; and when they were thus protected, I fitted them as neatly as I could into the unglazed frame again, and so got it ready for exhibiting. At half-past twelve o'clock that night, we went supperless to bed, laughing that we had so well conquered our terrible misfortune.

"Can't you contrive to dream that you've had your breakfast before we get up in the morning," said my patient and affectionate little partner as cheerfully as ever.

"I never felt any the less hungry for such a dream," said I, "but suppose we try, darling."

We didn't succeed though.

R. A. S.

Mechanics.

THE BOW TENT.

Dear Sir,—If you consider the following contrivance for a tent worthy the attention of your readers, it is at your service. Its principal advantages are lightness and commodiousness. I must not take up your space by going into those minutiæ which every mechanical mind will supply, but will merely state the principles upon which it is constructed.

A box 18×18×4, opening with card-table hinges across the middle, forms the table. In the four corners are four square holes, placed in a diagonal direction to receive four rods, jointed with square ferules. These rods support the table and form the support for the tent, which is of a cubical form, 36 inches in dimension or would be so, but that the front staves are twelve inches higher than the back ones, to give head room. All this is common-place enough. The peculiarity of my tent, which I will call the Bow Tent, consists in these four rods being strained into the form of bows bending outwards by strings simply contrived for that purpose, by means of which the calico is stretched tight at the top and sides, and the legs are stretched out so as to form a firmer support.

The front bows being the longest, extend back, so as to form a canopy for the accommodation of the artist, who ties *himself* into, or *the light* out of, his tent, as occasion requires, by means of a string, which runs in a "hem" round the aperture. The bow system gives great rigidity to the tent, the legs of which, forming the lower part of the bow, taper from $\frac{7}{8}$ to $\frac{5}{8}$, and the upper portions taper for $\frac{5}{8}$ to $\frac{3}{8}$.

The covering, and a 12×10 plate camera, pack easily into the box, while the legs are bound up with the tripod stand.

Spoon Plate-Holder.

Another contrivance, which may perhaps be of more general utility, is a plate-holder which I will designate from its form the Spoon Plate-holder. I have really found great convenience from its use in the almost perfect freedom from finger stains which I have enjoyed since its adoption. I use it principally for developing, &c. plates 12×10 and under, to which it adheres with great tenacity, and it is useful in drawing plates out of grooved boxes, for which its form adapts it.

A tin pipe, with a bore as small as possible (the tube and bore being about the size of the tube and bore of a tobacco pipe) is fixed to a tin disc, about $2\frac{1}{4}$ inches in diameter, which is perforated to correspond with the bore of the pipe. On the other side of this disc, the convex side, for it is slightly hammered, a rim $\frac{1}{8}$ of an inch high is soldered $\frac{1}{4}$ of an inch distant from its circumference, and a "ribbet" is thus formed, round which an annulus of india-rubber $\frac{3}{16}$ of an inch thick, $\frac{1}{4}$ inch wide, and about $1\frac{3}{4}$ diameter is stretched, and if necessary cemented with marine glue; the other extremity of the pipe, at six inches from the disc, swells out into a semi-cylinder 3 inches long and $\frac{5}{8}$ or $\frac{3}{4}$ inch diameter, round the outside of which a thin piece of wire is soldered to strengthen the mouth of the cavity.

A piece of vulcanized india-rubber tube, $\frac{1}{2}$ or $\frac{5}{8}$ of an inch diameter, is then slipped over the semi-cylinder—the tighter it goes on the better—and tied at both ends: a drain is thus formed at the handle of the instrument, and if, when it is grasped, the extremities of three or four fingers are thrust into it, the india-rubber annulus being gently pressed upon the surface of the glass to be raised, a very strong adhesive power is produced, which I have never yet known to fail. As a precaution, however, the thumb can be pressed lightly on the vulcanized india-rubber, the concavity of which will, of course, be a measure of the adhesion of the instrument.

The handle and tube being nearly in the same plane with the surface of the india-rubber annulus, the fingers are quite out of the way of any liquid that may run off the plate.

To any person who wishes to have one of these holders made, and I strongly recommend a trial, I beg to suggest:—

1. The disc must be as curved as possible, the edge being a little turned back to allow the india-rubber annulus to lie flat on the glass.

2. The tube must be as small as is consistent with sufficient rigidity and a free passage for the air.

3. The semi-cylinder must be made to fit the three fingers, allowing for the vulcanized india-rubber, the object being to exclude as much air as possible.

To any one who wishes to purchase the holder without the trouble of superintending its manufacture, I beg to recommend Mr. Rendle, of Ilfracombe, who I have no doubt will supply one according to my pattern at the moderate charge of one shilling, without the india-rubber, which was what mine cost.—Yours truly, M. A.

Miscellaneous.

How the Telescope was Invented.—We have spoken of the telescope as an *enfant trouvé*. The matter of its invention is said to have been in this wise:—Once upon a time—two hundred and more years ago—the children of a spectacle-maker were playing with some of their father's glasses before his door. They poke them here and there, till—what is it they see? The distant steeple appears to be brought almost into their own street. Paterfamilias is apprised of the phenomenon. He verifies it, but it passes his philosophy to tell the youthful inquisitors "the reason why." Like a sensible man, he screws the glasses on to a board, casts a covering about them, and secures the fact. The "spyglass" played subsequently far too grand a *rôle* not to attract the envious glance of national rivalry; and we have, in fact, the same legend repeated by more writers than one, always, of course, with a patriotic change of the place. The learned and unfeeling *savans* of the present day declare the stories to be all fudge. "The number of competitors for this honour," observes Sir David Brewster, "affords the most unequivocal evidence that the telescope was brought into the condition of a portable and efficient instrument by steps so gradual, that no individual had any real claim to be considered as its inventor." Ugh! for the Herod of our Innocents of Invention! We claim the honour for our little Flemings, and crown Middelbourg as the "Stammort" of numerous and refined family of the Dollands of our day.—*Macmillan's Magazine.*

Varnishes.—Very superior varnishes are now made with a solvent composed of highly rectified alcohol and benzole, instead of using, in the common way, alcohol alone. The alcohol should be nearly pure, and equal portions of it and the benzole mixed together. The following are different varnishes made with gum-resins and the alcohol benzole solvent:—1. For carriage varnish—copal, 28 oz.; amber, 8 oz.; anime, 4 oz.; camphor, $\frac{1}{2}$ oz.; solvent, 1 gallon. 2. Varnish for external use—copal, 28 oz.; amber, 4 oz.; anime, 4 oz.; camphor, $\frac{1}{2}$ oz.; solvent, 1 gallon. 3. Furniture varnish—copal, 24 oz.; shellac (bleached), 8 oz.; olibanum, 4 oz.; camphor, $\frac{1}{2}$ oz.; solvent, 1 gallon. 4. Picture varnish—copal, 20 oz.; damer, 12 oz.; mastic, 8 oz.; solvent 1 gallon. 5. White hard varnish—copal, 8 oz.; mastic, 16 oz.; sandarac, 4 oz.; camphor, $\frac{1}{2}$ oz.; solvent, 1 gallon. 6. French Polish—shellac, 32 oz.; solvent, 1 gallon. 7. Another French polish—shellac, 32 oz.; olibanum, 4 oz.; solvent, 1 gallon. 8. Varnish for prints and maps—mastic, 16 oz.; sandarac, 16 oz.; Canada balsam, 4 oz.; solvent, 1 gallon. 9. Varnish for iron (to be applied hot—resin, 12 oz.; sandarac, 16 oz.; seed lac, 6 oz.; solvent, 1 gallon. Preparations of lacker—1. Sandarac, 26 oz., shellac, 6 oz.; turmeric, 6 oz.; gamboge, 1 oz.; solvent, 1 gallon. 2. Seed lac, 18 oz.; amber (fused 6, oz.; gamboge, $\frac{1}{2}$ oz.; dragon's blood, 1 oz.; saffron, $\frac{1}{2}$ oz.; solvent, 1 gallon. 3. Seed lac, 8 oz.; copal, 4 oz.; sandarac, 12 oz; turmeric, 2 oz.; aloes, 1 oz.; gamboge, 1 oz.; dragon's blood, $\frac{1}{4}$ oz.; solvent, 1 gallon. The benzole and alcohol should be previously mixed together in equal parts, and distilled together with 7 ounces of caustic lime to each gallon. The gum-resins should be reduced to as small pieces as possible before being fed into the solvent.—*Scientific American.*

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 28th August, 1861.

M. Jules Duboscq has invented a portable form of camera for taking fifteen views on one and the same collodioned plate, with a single achromatic lens. He gives the name of *Travelling Policonograph* to this apparatus, and as far as one may judge from appearances, without actual trial, it seems well adapted to the object for which it is contrived.

At the last meeting of our Photographic Society a description was read of an optical instrument invented by Signor Ponti, of Venice, to which he has given the name of *Alétoscope.* The object of this instrument appears to be the application of the principles of the cosmorama to photographic views, in presenting architectural subjects to the eyes of the spectator with the combined resources of a periscopic lens of very large dimensions, provided with a double diaphragm, and suitably illuminated so as to give a correct idea of the original, and to obtain an illusion and a relief based upon principles different from those of the stereoscope.

The Alétoscope is composed of an external casing which serves as a head-rest, and in the interior of which is a large periscopic lens fixed in a frame, which the spectator can move nearer or farther from the picture by means of a couple of screws in the sides of the frame. To diminish aberration and avoid chromatism, one or two diaphragms are placed behind the lens.

The external case is in the form of a truncated pyramid. At the bottom it has a black frame, which covers the white border of the photographic picture, which is introduced by a lateral aperture.

Two large glass reflectors may be arranged at the proper angle to project upon the photograph the light from a window or from a gas-burner placed above the instrument, in front of the photograph, and at about four inches above the case.

The effect is much more brilliant in proportion to the greater intensity of the light with which the photographs are illuminated, consequently the very best effect is obtained by exposing the reflectors to the direct light of the sun, or in bringing the upper reflector to within four inches of the gas-burner.

To render the working of the instrument more convenient, when viewing pictures that are higher than they are broad, and *vice versa*, the anterior part of the case rests upon a circular disc worked by two pullies, and on a pivot in the centre of the back portion. By this arrangement it is very easy to turn the whole instrument through the quarter of a circle, by lowering the screw, and pressing the hand on the circular salient portion. There can be no doubt that this instrument is capable of affording much agreeable and instructive occupation for stay-at-home travellers.

It is very desirable that the poisonous substances at present employed in the photographic laboratory should be got rid of, if possible. There are those who maintain that one at least, cyanide of potassium, may be dispensed with, and now M. Jourdain proposes to relieve us of another, bichloride of mercury.

He says, that after employing all the ordinary means of making his picture appear on the negative after *disiodizing* and complete washing with rain water, when requiring a very intense negative, as of an engraving for instance, he pours alternately upon the plate solutions of sulphide of potassium, and of sulphate of iron. Great care must be taken to wash the plate thoroughly after each application. In this manner he obtains negatives in which the blacks are perfectly opaque, so that even the sun cannot be seen through them, and which consequently give perfect whites on the positive proof, which comes so clear and transparent that it appears as if made with printing-ink.

M. Bertsch has introduced an automatic camera for taking microscopic pictures, upon which he remarks:—"I have for some time past occupied myself greatly with taking portraits, which are so small, that they are only visible with the assistance of a microscope, and which jewellers can set in finger-rings."

Focussing images, which have scarcely the diameter of a pin's head, is certainly one of the most difficult operations of photography. For as we must take into consideration both the chemical focus and the refraction from the wet film of collodion, it can only be obtained after numerous difficult attempts. We also know that even when once obtained, this focus is strictly correct only for objects at the same distance from the camera, which becomes an impossibility when we commence this delicate operation anew, for we generally make a proof either larger or smaller than that first obtained.

M. Bertsch's new automatic camera is based on the same principle as his automatic camera for landscapes, which are to be enlarged in the solar camera. As with this latter, it is only necessary to place this little apparatus, which is a true "instrument of precision," before the object to be copied to obtain a very small image, remarkable for its sharpness. This is accomplished without focussing, for all objects more than 40 inches distant from the instrument, taking the single precaution of placing the camera exactly opposite the object, which is easily performed by means of a level mounted on the instrument. Portraits thus taken, although of microscopic dimensions, are perfectly modelled, and the little landscapes display the finest detail, although of no greater dimensions than a threepenny piece. This ingenious instrument will, doubtless, be gladly welcomed by photographers generally, as it will popularize a charming application of their art, which hitherto has been a monopoly in the hands of a few.

Our Photographic Exhibition, which seems to increase in attraction, rather than diminish, will not close until the end of September. A lottery in connexion with it has been authorized by the proper powers. The price of the tickets is fifty centimes, the number being limited to 10,000. There will be 150 prizes, consisting partly of the principal works in the Exhibition, a good number of other proofs of various subjects, some microscopic pictures mounted as jewels, several large American stereoscopes supplied with pictures now in the Exhibition, and other stereoscopes, with and without stands, furnished also with pictures. The drawing will take place on the twenty-fifth of November next.

M. Giovanetti, in competing for the prize offered by M. le duc de Luyues, has prepared some proofs, part by means of an oil varnish, and part by means of writing ink. He has not described his positive processes, but in indicating certain details of his process for obtaining negatives, it appears that they are obtained on dry collodion without bromides; and that for more than a year past he has made use of a developing solution to which he adds gallic and pyrogallic acids, and tannic acid dissolved in alcohol.

The Imperial Commission on the forthcoming Exhibition of 1862 has appointed the following persons as the Jury on the section of photography:—

M. Bayle Mouillard	*President*, Conseiller de la Cour de Cassation.
,, Delessert (Benjamin)	*Vice-President*, Member of the International Jury of 1855.
Aguado (Count)	Member of the Photographic Society.
M. Bayard	Ditto ditto.
,, Bertsch	Ditto ditto.
,, Courmont	Chef de la division des Beaux Arts, du Ministère d'Etat.
,, Davanne	Chemist.
,, Delessert (Edward)	Member of the Photographic Society.
,, Duboscq	Optician.
,, Girard (Aimé)	Conservateur des Collections de Chimie à l'Ecole Polytechnique.
,, Hulot	Directeur de la fabrication des Timbres-poste a la Monnaie.
,, Mailand	Member of the Photographic Society.
,, Niepce de Saint Victor	Chef d'escadron, Commandant Militaire du Louvre.
,, Robert	Chef des Travaux de Peinture à la Manufacture Impériale de Sèvres. Professeur de Photographie à l'Ecole des Ponts et Chaussées.
,, Kely d'Oissel	Auditeurs au Conseil d'Etat.
,, De Villeneuve	*Secretaries.*

SUNDAY PHOTOGRAPHY.

Dear Sir,—Seeing in to-day's Photographic News that you would be glad to have the opinion of every respectable photographer respecting Sunday photographing, as regards touting photographic dens, I beg to offer a few remarks on the subject. The annihilation of these dens is a subject in which every respectable photographer is interested. Speaking from five years professional experience in photographic portraiture, more especially both in the Midland Counties and also in the West of England, it is my opinion, that the general public do not know good photographs when they see them, but are rather contented with pictures having the least possible resemblance to the parties whom they are meant to represent, which pictures, as if ashamed of their own ugliness, rapidly fade and disappear. Hence not unfrequently are respectable photographers asked by their customers, who have paid a fair and legitimate price, are you sure that this picture will stand and not fade? and been answered in the affirmative, say, because about two or three months ago I had a little portrait of myself taken by Mr. So-and-so for sixpence just to see how I looked, and the picture is all gone, and I have only the glass left, and I should be very sorry to give so much for a portrait, and for this one to go in the same way. Because bad photographs fade, the public very naturally think that good photographs, and those which are finished in a proper and skilful manner do the same, and dislike to lay out much money on that which they consider to be of doubtful permanence.

There is I think one way of ridding the country of these photographic dens, and the profession of men who would be a disgrace to the meanest mechanical calling; and thus removing from the art the stain of producing pictures which after a few months will fade.

The remedy I suggest is this: let a petition be got up respecting this Sunday-trading and unfair competition, and let every respectable professional photographer throughout the country sign it; let a licence be required for the practice of the art *professionally*, varying from £10 to £20 per annum, according to the size of the locality; we should then very soon find that the profession would be rid of those worthies who caricature you for sixpence. The art would assume a more respectable and dignified position, and first-class respectable photographers would be able to command better prices than they can now for their productions. I think it is evident from the conduct of Her Majesty's Commissioners in reference to photography at the coming Exhibition of 1862, although this has nothing to do with the matter in question, further than it shows that the public will not honour the art; and that what is done in reference to the matter of ridding the profession of these worthies must be done by photographers themselves.—I remain, dear sir, yours truly, T. S. Swatridge.

Princes' Street, Yeovil, August 24th, 1861.

Dictionary of Photography.*

Reflection.—When light falls upon any body a portion of it is thrown back from the surface or reflected, the remainder suffers absorption and reflection. All bodies reflect light, and it is only by the light they reflect that they become visible. The amount of light reflected by bodies depends on the nature of the surface, and the angle at which it is received. Every point in an object which receives light reflects it again in all directions, and thus renders the object visible, by some portion of this light entering the eye, from whatever point it may be viewed.

Direct light incident upon any plain polished surface is reflected from that surface at exactly the same angle at which it is received, the angle of incidence and reflection being always the same. A line drawn so as to strike a reflecting surface exactly at right angles is called a *normal*, and a ray of light striking the reflecting surface from such a direction as would form an angle of say forty-five with this normal, on the right hand, would be thrown off or reflected at just the same angle from the left side of the normal. The angle formed with the normal and the direct light is called the *angle of incidence*, and the angle formed with the normal and the light thrown off is called the *angle of reflection*.

This law of incidence and reflection appears at first sight only to apply to polished or mirror surfaces, which reflect light in the manner described, whilst irregular surfaces reflect it in every direction, the law really holds good, however, in all cases. Light is reflected in all directions from bodies possessing irregular surfaces, simply because these surfaces receive it, from their irregular form, at all angles, and thus throw it off at all corresponding angles. The bulk of the light, moreover, thrown off by bodies, and by which all their details of form and texture are rendered visible, is diffused or reflected light. If objects were only illuminated by the direct light of the sun without the aid of reflection, the contours only of anything would be visible and such of their details as were next the source of light; all the rest being total blackness or darkness. It is only in bright sunshine, however, that objects are illuminated by its direct light; the clouds, the atmosphere, every object upon which light falls, becomes a source of reflected or diffused light, and renders objects visible in their entirety of form and detail.

Reflecting mirrors, or prisms, were at one time, when daguerreotypes were taken, much used for the purpose of obtaining a direct or non-reversed image in the camera. By the law of reflection, which we have stated, it will be evident that a mirror placed with its reflecting surface at a suitable angle with the lens would give a non-reversed image in the camera. This practice is now, however, abandoned, as the negative obtained in a reversed position gives correct images by reversing them again in printing; and in glass positives non-reversed images may be obtained where it is desired by other means.

Reflected Lights, or Reflexes.—Those lights in a picture derived from any other than the direct or principal source of light, are called reflexes or reflected lights, and form one of the most important elements in the truth and beauty of chiaroscuro of a picture, whilst they are the chief agents in giving the effects of roundness, relief, and texture. The appearance on every object is materially modified by the character and position of the objects by which it is surrounded, and which reflect light upon it in degrees, affected by their colour, surface, and position. To the artistic photographer no subject of study can be more important than the native value of reflected lights. Perhaps nothing has contributed so largely to the worthlessness of many composition photographs than the entire inattention to this point. In a group of figures as actually placed, the effect of each is materially modified by the reflexes from each other. In the composition picture produced from a number of parts taken at separate times under varying conditions of direct light, and entire absence of all the conditions of reflected lights true to the subject, the truth of nature is altogether violated, and the result cannot fail to be unsatisfactory even to those least able to define the cause to which the manifest defect is due. We strongly commend the study of the value of reflected lights to the artistic photographer.

Photographic Notes and Queries.

Blisters in Albumenized Paper.

Sir,—Your last contained an enquiry by "T. P. E." respecting some difficulties with a sample of albumenized paper.

Perhaps, in the absence of any other explanation, the following may be found a reasonable solution of the difficulty.

The paper has in all probability been salted with chloride of sodium, sufficient care has not been taken to amalgamate the salt with the albumen, or from some other cause crystals of salt have remained in suspension in the albumen. Now these crystals containing a certain amount of moisture, on the application of the silver bath to the surface of the paper, the albumen layer above these crystals swell, and, where the salt may be in excess, ultimately break, exuding their moisture—which, combining with the silver in larger quantities than in other parts of the paper, cause the stains—which are, in fact, darkened chloride of silver.

Should this suggestion prove correct, the paper is, of course, valueless for obtaining good proofs; it might, however, be worth while to dry a few pieces carefully by exposing the back of the paper only to the fire, and then floating them for a very short time on a tolerably strong silver bath; but there could never be anything like certainty of obtaining clean proofs.

Should you consider this suggestion a reasonable one, you can use it in any way you may think proper.—I am, sir, yours respectfully, E. E. L.

P.S.—It may be a question worth consideration if blisters do not, in most cases, arise from particles of matter imprisoned between the albumen and the surface of the paper. If we gum or paste a proof on a mounting-board, and the surfaces are not completely in contact, those parts where the adhesion is imperfect on receiving a wash of colour or moisture of any kind, will rise up and form blisters; those blisters generally subside on the proof drying, but in some cases will not do so. I think, sir, such cases are analogous to the blistering of the albumen film, and that we need seek no cause in the chemistry of the process.

[The suggestion of our correspondent regarding the blisters in the paper mentioned last week, is probably correct. The stains resemble blackened chloride of silver free from combination with organic matter.—Ed.]

Talk in the Studio.

The "Elephantinon" Process.—This is the name given —for what earthly reason we cannot conceive—to a very effective method of colouring, or rather of treating coloured photographs, whereby they are made more nearly to resemble ivory miniatures than anything else we have seen. The photograph, tinted in water colours, undergoes the process, and at once acquires the softness, delicacy, and transparency of ivory. The process is, we understand, the subject of a patent, and, as may be ascertained from an advertisement in another page, is taught and practised by Madame Una Howard.

Photography *v.* Biography.—The *Athenæum* in a somewhat ungenial notice of a recently published biography of John Brown, whom American abolitionists regard as the protomartyr of the "irrepressible conflict" or great anti-slavery struggle, remarks, "The present volume is adorned, more or less, by a photograph of John Brown, which, after all, offers the best apology for his character. Everything about it evinces a dogged unreasonable obstinacy, a determination to be a martyr; in fact, the portrait gives a better idea of the hero of Harper's Ferry than the four hundred and fifty pages of the text."

"The King of the Gorillas."—We have recently inspected some stereoscopic and other photographs of the "King of the Gorillas," described so graphically in the work of M. De Chaillu, and which is now in the British Museum. It is just about to climb a tree, one branch of which is grasped by its gigantic outstretched arm, the head is turned, with open mouth and glaring defiant eye, on some assailant. Nothing could present a more striking idea of this hideous travestie of humanity which has recently excited so much attention, than the stereoscopic views before us. The repulsive head set right on to the immense chest, without any apparent intervention of neck, suggesting the "men whose heads do grow beneath their shoulders;" the cavernous angry eyes—the enormously long and powerful arms—the large unwieldy paunch—and dark shaggy covering—the whole so like, and yet so fearfully unlike, man—are all, in the different stereoscopic views, brought before us with quite as near an approach to life-like effect as one desires to see. They are published by Birnstingl and Co., the firm who secured the contract for photography in connexion with the International Exhibition.

Photography in New Orleans.—A correspondent, writing from Houston, Texas, requests us to intimate to Mr. Anderson, photographer, of New Orleans, that a letter awaits him in the care of Mr. Atkinson, Manchester Street, Liverpool. The blockade of the port of Galveston cuts off direct postal communication, and Mr. Stanley, of Houston, has adopted this as the best method of forwarding a letter. Regarding the interruption of postal communication, he says:—"Of the Photographic News I have received nothing since the early part of May. Possibly you may have heard that all postal communication between the Southern and the Northern States has terminated, and that you have ceased to forward my copy. When the British Post-Office Department forward mails to Southern Confederate States, I will thank you to continue my supply. Of the missing numbers, if any, I will give you a list, and the extra charge shall be liquidated in my next remittance. Requesting that you will oblige me in this (for a famine in English photographic news does not suit an English rapacious reader), and apologizing for troubling you,—I am, sir, &c."

M. Claudet and M. Silvy.—In M. Claudet's recent letter to the *Photographic Journal* respecting the classification of photography in the forthcoming International Exhibition, he has some pertinent remarks on M. Silvy's letter claiming for photography a purely mechanical character. He remarks:—"A photographer, who has the pretension to be an artist, has thought to distinguish himself by calling his art an entire mechanical work. I think very few photographers will be converted to his opinion, and accept as easily, and without protest, the undignified place offered by the Royal Commissioners which he is so anxious for. The same photographer has asked this very funny question:—*Would the constructors of locomotives have the right to enter the engines for the Derby in order to compete with thoroughbred horses?* He might, with the same propriety, have asked, why asses should not have also the right to compete with both; for photography has its asses as well as its horses and its engines. But let us not complicate the question; is not the comparison very strange coming from a photographer? Its defect is, that it signifies nothing, and is not in the least to the point. For my part, I object to be compared to a horse as strongly as to be compared to an engine. The horse runs in proportion to his bodily agility and vigour, and his spirit is excited by the spurs of its rider; but I do not think that the horse who has run the fastest has proved to have elicited more genius, more mind, than those he has left behind in the course. Both the horse and the engine may indeed be classified among the machines; and at all events the horse will not enter his protest. When the race is over, he will be more sensitive to a feed of oats than to the praises and admiration of those who have witnessed his velocity on the racecourse. Let us hope that in photographic aspiration there may be something more æsthetic than a *picotin d'avoine*."

To Correspondents.

G. Lewis.—So far as our own experience goes we should recommend No. 2 on your list.

W. W.—It is difficult to say with certainty either the cause or cure of blisters in albumenized paper. It generally happens with a very highly albumenized paper, and more commonly with a *Rive* paper, or an English paper, than with a *Saxe* paper. Alkaline solutions have a greater tendency to cause it than those which are acid or neutral. It has been suggested that it was caused by the partial solution of the size of the paper at the points where the blisters occur, thus separating the albumen from the paper. It has also been suggested that as it only occurs in very highly albumenized papers, and papers which from their own hardness support a thick layer of albumen on the surface, and not at all permeating the fibre of the paper, it arises from the albumen not being coagulated through the whole of its substance, but only on the surface; this being the case portions of the under surface, not coagulated, become dissolved, and thus cause blisters of coagulated albumen to rise from the surface of the paper. In many cases these blisters subside in drying and form no defect. Where they are so serious as to deface the print the only plan is to use another sample of paper.

Beta.—The silver bath, whether used for exciting collodion plates, or sensitizing paper becomes gradually weaker, as it is robbed of silver in greater proportion than of water. It is quite true each plate or each sheet carries away with it a certain quantity of solution, but it also takes in the form of iodide of silver, or chloride of silver, a certain quantity of silver, the water belonging to which is left behind. Keep replenishing your bath for collodion plates with a solution of about 45 grains to the ounce, and your paper bath from a stock solution of about 80 grains or 100 grains to the ounce, and test it now and then with the hydrometer to ascertain the strength. 2. There is no necessity to take the trouble to add an extra amount of iodide, afterwards to be filtered out, in making a new bath: leaving a large plate coated with collodion for a few hours in a moderate sized bath will generally be found sufficient. If the bath be a large one the process may be repeated again, using another plate. 3. If you develop with iron you may correct the bath with nitric acid, but be careful and do not add too much.

An Old Reader.—Unless you are familiar with the processes of working with leather and blocking it into forms, you will find black cotton velvet a much more manageable material for the extending body of your copying camera. If you prefer the skiver it must be lined with black calico, or it would soon be torn. Proceed to make the bellows-body as follows:—Cut the leather the right size, and paste the black calico to it to form the lining. Whilst wet double it into folds about an inch and a quarter broad, turning each alternate way. Now take the long strip of folds formed, and bend it together at the places where the corners will be formed, and then turn over a corner so as to form a fold of the shape of a right-angled triangle at each corner. If the leather be well pressed into these folds whilst wet, it will readily, when dry and opened out, be made into the bellows extending body, the folds merely requiring a little adjustment to make them assume the proper position.

Deposit.—We are very familiar with the deposit to which you refer. It occurs more frequently when intensifying iron negatives before fixing, than when the intensifying is done after fixing, and is most generally met with in hot weather. There are two or three methods of dealing with it. The first and simplest is to use citric acid in the pyrogallic acid intensifying solution; this, if the acid be in sufficient quantity, will frequently prevent it. Another method which we have generally found to be successful is, after washing away the iron solution thoroughly, to pour over the plate a solution of iodine, made by adding alcoholic tincture of iodine to water in sufficient quantity to make it a deep yellow tint, or to use an aqueous solution of iodine altogether, 1 grain iodine, 1 grain iodide of potassium, to an ounce of water. After covering the plate with the iodine solution, hold it for a second or two to daylight; then wash and intensify. We have never met with a deposit after this treatment. In cases where a slight copper coloured deposit has occurred on the shadows notwithstanding every care, it may sometimes be removed by stopping the intensifying at once; and in fixing, pour the cyanide solution repeatedly over the part. Or should this method either fail or appear too dangerous, the effect of the deposit in printing may be almost entirely neutralized by pouring over the plate after fixing and washing, a dilute solution of bi-chloride of mercury, not for the purpose of intensifying, but for changing the colour of this foggy deposit from brown to white, which will then scarcely interfere at all with printing,

An Operative Chemist.—We cannot advise you as to the particular branch of photography best suited for the employment of your leisure hours, as that must depend so much on a great variety of circumstances: your own tastes and abilities, and the openings to which you have access must guide your decision. A lightish grey is the best colour for a background for collodion positives. A 40-grain silver bath is strong enough for either positives or negatives; a greater strength only increases the difficulties of working cleanly. About 130° Fah. we should call a low temperature for the manufacture of pyroxyline Many articles on the negative process have appeared in our pages, which you may read with advantage. Read the article on "Iron Negatives" in the present number, and the articles which will follow on the same subject.

Binocular and some other correspondents next week.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 157.—*September* 6, 1861.

IRON NEGATIVES AND BRILLIANT PRINTS.

The Nitrate Bath.

Having last week considered the conditions so far as they relate to collodion, upon which the production of brilliant printing iron negatives depends, we next have to deal with the nitrate bath; which we shall do very briefly.

A primary condition in a good nitrate bath for iron negatives is simplicity. With a good sample of nitrate of silver, a bath may sometimes be made thirty-five grains to the ounce, which will work satisfactorily immediately it is made and saturated with iodide of silver. As this is not always the case, we will briefly describe the mode of operation we generally pursue with success. We dissolve two ounces of the purest recrystallized nitrate of silver we can procure, in twenty-five ounces of distilled water, and filter into the bath. Then coat a large plate with the collodion we use, and leave it in the bath for half an hour or an hour; after which we try a plate. If it work well and give clean shadows, we submit it to no further treatment. If, as is frequently the case, there are streaks all over, and a deposit on the shadows, we try the bath with test paper. If it be neutral, as with a good sample of silver it is often found to be, one drop of dilute nitric acid—one part nitric acid 1·420 to three of water—is added, and another plate tried. This operation is repeated until clean shadows and freedom from streaks is produced. This result is generally secured by the addition of few drops of the dilute acid. Should more than this be required, or should the bath on testing be found to have a decidedly acid reaction and still produce fogged shadows, we look for the cause in something beyond the want of sufficient acid to prevent spontaneous or over-rapid reduction. Some trace of organic matter is probably present in the sample of silver or in the distilled water. The bath is at once rendered alkaline with oxide of silver. We do not find it necessary to use this freshly precipitated, but keep a small quantity in a bottle of distilled water. When required for use, it is shaken up and a few drops of the turbid solution is added to the bath. The whole is well agitated together and then exposed for a few hours to sunlight. A slight black precipitate generally ensues; the solution is filtered, again treated with nitric acid, and except under unusual circumstances all then goes well.

Much has been said at times about the advantages of a neutral bath, and there can be no doubt that theoretically it is favourable to rapidity. In practice, however, it is rarely found to possess much value, as it involves the necessity, to ensure clean results, of old collodion containing free iodine and a considerable amount of acid in the developer. Where iron is used, the presence of a slight amount of acid in the bath is absolutely necessary for satisfactory working. The exact amount is, as we have said, best ascertained by actual experiment. Sufficient to produce a slight reddening of blue litmus paper will not, if other things are in suitable condition, cause any sensible diminution of rapidity; but the safest rule is to use as little as it is possible to have, and yet obtain clean shadows.

We decidedly prefer the use of nitric acid with iron development to acetic acid. There are many reasons, theoretical and practical, for this choice. Where a pyrogallic acid developer is used, the presence of an organic acid, and even an organic salt of silver in the bath is a decided advantage. But with iron development the harmonious relation of bath and developer are best preserved by the use of the inorganic acid, whilst the full value of a bromide is best attained under the same circumstances. The practical advantages wil be very apparent if it be borne in mind that we are endeavouring to preserve the bath in as simple a state as possible.

Acetic acid once admitted into a bath is most difficult to eliminate. If it be necessary at any time to neutralize the solution, acetate of silver is at once formed, which we desired to avoid. Nitric acid on the other hand, either added too freely, or liberated by the continued use of a collodion containing much free iodine is easily neutralized, and the bath placed in its normal condition. It is important to possess this power, as it sometimes happens that under certain conditions a bath rapidly deteriorates. We were informed by one of our first photographers the other day that the collodion he was using would spoil a good bath in one day's operations with 12 by 10 plates. Whilst an exposure of twenty seconds gave good results in the morning, an exposure of eighty seconds was necessary to the production of equal results in the afternoon, without any sensible change in the quality of the light.

So far as we could judge from the symptoms, the liberation of nitric acid in the bath by a collodion possessing free iodine was the cause. With a bath containing nothing but nitric acid this might easily be remedied, but if acetic acid were present the whole case would become more complicated. Since, then, there are decided practical conveniences obtained, and since, with a bromo-iodized collodion and iron development the results are equal or superior in rapidity and quality of image when nitric acid, in place of an organic acid is used, we give the decided preference for every reason to the former.

Where pyrogallic acid is used for development, and especially with certain kinds of collodion, the presence of acetate of silver in the bath may frequently be found advantageous, and tend to the production of brilliant negatives. Where it can be avoided, we do not like it in a bath when iron development is used. It unquestionably aids in obtaining that density, which it is sometimes difficult to attain with iron. It has frequently, however, a slight tendency to interfere with sensitiveness, and occasionally with cleanness. It is quite possible, by a careful selection of the collodion, to obtain sufficient intensity, especially by the aid of after processes, with iron development in a bath prepared as we have described, pure and simple. The bath is then at all times easy to deal with, and the negatives have generally a delicacy not easily attainable, where organic salts of silver are present in the bath.

We recently stated the results of some experiments with the addition of free iodine to the nitrate bath as suggested by the Abbé Laborde. The object proposed—the production of unveiled shadows in a neutral bath—was so desirable where iron development was used, that we considered it worth a little effort to prove it satisfactorily. We have made a few further experiments with precisely similar results to those stated. In the hands of one or two friends skilled in such manipulations, the same conclusion has followed careful experiment. Free iodine added to a neutral solution of nitrate of silver, whether already saturated with iodide of silver or otherwise, has simply combined with the silver and liberated nitric acid. There is nothing, therefore, we fear to hope from that suggestion.

There are cases in which, from the presence of some unknown impurity—some sulphur compound of silver has been suggested—every effort to make a bath work cleanly and rapidly is unavailing. Insensitiveness and fogging characterize the bath, which is quite new, or has been worked but a day or two. And there are a variety of other difficulties with the bath, which occur in the course of use. But we are not dealing with the general question of the derangements the bath is incident to, but rather pointing out those conditions most desirable to secure for the production of thin, but brilliant iron negatives. This, in our own practice, and in that of some of our most operators, is found in the bath we have described, and which we commend to those of our readers who practice iron development.

Next week we shall have something to say as regards the operation of light and development in this process.

NEW APPLICATION OF PYROXYLINE.

A novel and somewhat singular application of pyroxyline is described in the specification of a patent recently obtained by Mr. S. Barnwell and Mr. A. Rollason, for "Improvements in Combining and Mixing certain Solutions of Pyroxyline with Animal, Mineral, and Vegetable Substances, by which its quality is altered in such Manner, as to produce Hard, Resistant, Adhesive, Plastic, or Resilliant Compounds and Articles unalterable in their Nature, and varied in Colour, which said Compounds in a State of Solution may also be advantageously employed as Paints or Varnish."

As a method of utilising the waste acids accumulating in the manufacture of pyroxyline is proposed, it may prove interesting to many of our readers; and we shall make sufficient extracts from the specification to explain the purpose and *modus operandi* involved in the patent.

It will naturally occur at the outset to the minds of all who have experimented at all in making pyroxyline, that it is a somewhat expensive material to use for manufacturing purposes in the place of gutta percha, vulcanite, &c.—for it is in the place of such substances we presume it is to be used—but we glean that not only may the waste acids from the manufacture of photographic pyroxyline be used, but that these may be used over and over again. The specification states:—

"With reference to the pyroxyline itself, and its manufacture, which has hitherto been effected by a difficult, uncertain, and expensive process arising from the fact that the mixed acids, nitric and sulphuric, used in converting the fibre into pyroxyline could not be employed more than twice in the same operation, as they would be found to hold either a considerable quantity of pyroxyline or converted fibre in suspension, or that the nitrogen was partially exhausted, or from both these evils together; consequently, after twice using, these acids were of no further service for such a purpose. With the view, therefore, of utilising these waste acids we employ as our fibre, and in place of cotton wool (which we can employ, although we prefer the following) common rags of any description, plain or coloured, and having submitted them to the action of the acids in the same manner as cotton, we find that they do not become disintegrated as the cotton would, and consequently after twenty or twenty-four hours' contact with the acids, the acids may be drawn off free from any suspended pyroxyline.

"The partially exhausted acids are then put in suitable air-tight vessels, until a sufficient quantity may have been reserved. The bulk is then to be thoroughly and evenly mixed and boiled, then analysed, and the loss of strength ascertained; after which, the equivalent must be supplied by the introduction of very strong fresh acids in the requisite proportions, by which they will be restored to their original strength, when they may be re-used. This re-use and renewal may be repeated as often as may be found desirable. This is the description of pyroxyline we prefer to employ in our subsequent processes of manufacturing compounds of pyroxyline into various useful articles, though any description of pyroxyline will also answer these ends; but, as before stated, at greater cost.

"We also obtain a very useful description of the same article by submitting fibrous and others matters containing celluloso to the action of mixed acids of such modified strength and temperature that they will be only partly converted into pyroxyline, and, consequently, they will be only partly soluble in the solvents of pyroxyline; this forms a kind of half-stuff. But in all cases both the pyroxyline and the partially converted fibre or half-stuff must be freed from acids and dried before advancing to the further processes."

Regarding the purposes to which the pyroxyline thus produced is to be applied, we learn that:

"The invention consists in dissolving pyroxyline in any of its known solvents, and adding thereto oils, animal vegetable, or mineral, varying in their nature and their action, with pyroxyline, selecting any of these to suit any particular views we may entertain relative to the subsequent use of the compound. To this we add, if desirable, gums or resins, and also oxidisable salts, such as oxide of manganese or oxide of copper as colouring agents. Any other suitable colouring may likewise be employed. Other mineral substances, such as chloride of calcium and iodide of cadmium, are useful when articles of an uninflammable nature are to be produced. Animal matters in the shape of glue, gelatine, or wool flock, or of nature similar to these, we also find useful for the purpose of strengthening the compound. The material resulting from these combinations is applicable to the manufacture of many solid, hollow, or tubular articles that have hitherto been made of glass, china, metal, wood, india-rubber, and such like materials, and the treatment of the compound for the purpose of making such articles would vary with the nature of the article to be produced; for instance, buttons may be made either by stamping them from a solid sheet of the new material after the manner of horn button making, or they may be shaped in moulds whilst the material is in a plastic or semi-fluid state. So with drinking cups, bowls, and flasks, which may be made by coating either the inside or outside of glass or polished metal moulds with repeated layers of the new compound in a state of solution, or by the mode by which pressed glass is made; the material being used in a plastic state, in which state also it would be found very useful for employment in moulding or taking fine casts, such as those required for purposes of dentistry and modelling for jewellers, goldsmiths, and other industries needing sharp, smooth, and undestructible models or moulds. It may also be employed for making tubes and instruments for surgical and hygienic uses. Cups, bowls, tubes, and such like things may also be made by coating textile fabrics with our solution, and then cutting such fabric out into the desired shape, and afterwards cementing the edges; or the raw material of such textile fabrics may be saturated with our solution, and from which various articles may be produced.

"In the solid form in sheets it would be useful for bookbinders and fancy box makers, for making collapsible tubes for colours, and for all the purposes for which collapsible tubes are used; and as it can be rendered adhesive by some of the modifications already mentioned in the manufacture, its applications in this form would be multifarious.

"In a state of solution its uses would be as a vehicle for pigments, either oil or water, or as varnish for pictures, painting, prints, or papers, a lacquer or wash for gilded or plated wares, whether on wood or metal, to protect them from injury; as a coating for hat bodies, for boots, shoes, and leather in general; lining or covering plastic casts, pens, telegraph wire, and all delicate parts of machinery requiring protection."

In addition to these proposed contributions to the arts of peace, we find that this form of pyroxyline is once more to become literally *gun*-cotton, and assist in producing, instead of attempting to supersede, gunpowder:—

"In the manufacture of gunpowder we find pyroxyline extremely useful, and this forms one of the most important applications of our invention. We take dry pyroxyline, and reduce it to powder, in which state we employ it in place of or in conjunction with charcoal in the manufacture of a gunpowder. This, from the highly explosive character of the material, adds very much to the strength of the gunpowder, whilst it avoids, to a very considerable extent, if not altogether, the residuum that remains after the discharge of ordinary gunpowder, and at the same time is free from the danger attending the use of gun cotton."

The name of the purposes to which this new preparation of pyroxyline is literally legion, and seems to include every possible or imaginable article to which a plastic material can be applied. We shall conclude by extracting just one paragraph out of several, enumerating its uses:—

"Articles of apparel of every kind, umbrellas, parasols, cart covers, tents, sails, machine bands, straps, belts, tubes, harness, for bookbinders' uses both as a cement, and also as a material for the covers of books; air and water bed and cushion covers; sponge and other bags; cups, bowls, basins, and jugs; to protect cartridges, caps, and projectiles from damp; for bottles, boxes, and jars; for surgical and dentistical purposes, as well as for the manufacture of sticking plaister and surgical instruments, and for any other purpose analogous to or of a kindred nature to any of these; in a pulverized state as a substitute for charcoal in the manufacture of gunpowder. In the state of varnish or lacquer it may be used for wood, papier-maché, leather, metal, bricks, stone, plaster, glass, china, earthenware, bone, ivory, india-rubber, gutta-percha, gelatine, and all other articles made of or similar to these, or of a nature akin to these. For rendering impervious to the action of the atmosphere all articles desired to be preserved; for finishing and stiffening every description of paper and pasteboard; as a varnish for oil and water-colour paintings, and a vehicle for pigments; for sheathing for ships, and roofing; for saturating articles or goods requiring it; and, generally, for any and all purposes of a like nature to those we have already enumerated."

ACCIDENTS WHICH OCCUR IN ENDEAVOURING TO OBTAIN MAXIMUM SENSIBILITY.*

BY M. MC. A. GAUDIN.

After substituting a porcelain dish for the one of gutta-percha, and preparing a bath of solution of fused nitrate of silver slightly accidulated with nitric acid, I succeeded in obtaining negatives in the tenth of a second with a compound stereoscopic lens, with a diaphragm of $1\frac{1}{2}$ inch, but I still had some little spots caused by crystals. Supposing these latter had fallen upon the collodion film, I sensitized the plate with the collodion, side downwards on the bath, but the spots and holes continued to appear, nevertheless.

I again thought of adding some acetate of lead, hoping by this to provide a remedy for the annoyance; but none happening to be in my laboratory at the moment, I added to my bath, with the same object in view, a few drops of acetic acid, thinking to obtain thereby at the most an almost instantaneous diminution of sensibility, and at all events the same degree of purity in the proofs. But it was not so; the bath completely ceased yielding pictures, not from extreme slowness, but from a complete fogging. I attributed this extraordinary result to a reducing substance present in the acetic acid, to *acetone*, which may probably produce this effect.

Fortunately, I had modified only one half of my bath, the other portion having also yielded me negatives spotted with holes in the same manner as the first, I added a trace of *nitric* acid to it instead of acetic acid, expecting to find a retarding effect as the result, but still very clean pictures; but, to my great surprise, the result was exactly the same as when I added acetic acid, it was not possible to obtain the slightest trace of an image. These facts appear to me very extraordinary: I have mentioned them to some experienced photographers, who tell me they have observed the same effects. I must confess, however, that I did not take into account the possible impurity of my nitrate, which, prepared from a button of metallic silver in the crucible, contained iron, zinc, cadmium, &c., but I do not think this was the cause of failure.

Having thus rendered my bath insensible, I wished to restore it by the moist way. I precipitated the silver by carbonate of soda, and redissolved it with nitric acid. Upon experiencing some difficulty in saturating this new bath with iodide, I precipitated a large quantity in the silver solution, and after agitating it for some time, carefully filtered it. I was certain of having obtained this saturation; nevertheless, the layer of iodide upon the sensitized plate was quite imperceptible, and cut by a transparent horizontal line (where the iodide of silver was deficient), at the height of the level of the bath, when the sensitized plate, collodion side downwards, was raised vertically to drain.

This time the negatives were of remarkable purity, but it took fifty times longer exposure to obtain them. I was certainly well aware that my bath was weak in silver, but I did not think that this thin layer of iodide and the slowness of impression was due solely to the weakness of the bath; but upon washing the last proof, after having fixed it, the stream of water detached the image without removing the collodion, affording a certain proof that the bath had become exceedingly feeble, perhaps reduced to 2 or 3 per cent.

Thus, when the silver bath is exceedingly feeble, not only is the layer of iodide detached, as is well known, but it is not wholly formed, and the sensitiveness is reduced in an extraordinary degree in consequence of iodized collodion still remaining under the layer of iodide of silver formed on the surface; for in my last experiment I had not a fourth of the opacity proper to the collodion I employed, and which I obtain immediately when making use of a strong silver solution. From this, I conclude, that, in all probability, the sensitiveness is in proportion to the strength of the nitrate bath, and that probably a bath of the strength of twenty-five per cent. would yield such advantages in this particular as to cause it to be preferred in taking portraits The examination of this question I shall undertake in my next essay.—*La Lumière.*

Scientific Gossip.

When photography was in its infancy it was not a difficult matter to get chemicals free from adulteration. The demand for them for photographic purposes was so small that it was not worth while for any one to take the pains to palm off an inferior article as pure to get merely a trifling profit. Now, however, things are different. Tons weight of substances are consumed at present, where pounds were formerly used, and adulteration, the great commercial curse of the present day, revels in the photographer's laboratory. Amongst the other chemicals which have greatly deteriorated of late years is hyposulphite of soda; the difficulty of detecting any of the salts of other sulphur acids being a great temptation to an unprincipled manufacturer to send the article out incompletely purified, or even largely adulterated with other salts. Of these sulphur acids the most injurious is sulphurous acid, which in the form of sulphite of soda, is a very common as well as a very injurious contamination. Up to a very recent period there was no test for its presence in hyposulphite of soda which could be easily applied by an amateur, but within a few weeks a very excellent reagent has been made known, by means of which we have ascertained the presence of sulphite of soda in several samples of commercial hyposulphite, of which complaints had been made by photographers as to their imperfect fixing properties, and liability to stain the prints. The test is founded upon the reaction which takes place between nitroprusside of sodium and sulphite of soda. When solutions of these two bodies are added together there is produced a pale rose colour which is much more distinct when an excess of sulphate of zinc has been previously added to the solution of nitroprusside; but an intense purple red is produced when a small quantity of yellow prussiate of potash is added to the mixture. This reaction may be applied to the detection of sulphurous acid in hyposulphite of soda or other bodies in the following way:—If the salt to be tested is not neutral it is first neutralised with acetic acid or bicarbonate of soda; an excess of the latter is not objectionable, but an excess of either caustic or carbonate of soda, or of carbonate of ammonia prevents the reaction. If any bases are present which give insoluble salts with sulphurous acid, such as silver, these must be removed. Then a proportionately large quantity of solution of sulphate of zinc is mixed with a very small quantity of nitroprusside of sodium, and added to the solution to be tested. When the amount of sulphurous acid present is not too small, a rose red, or dark red colour is soon produced; but if it is not very distinct the addition of some yellow prussiate of potash will give an intense red. In this way a most minute trace of sulphurous acid may be detected. Hyposulphite of soda or hyposulphurous acid under the same circumstances produce no reaction.

The action of a beam of light upon a mixture of chlorine and hydrogen gases was lately very beautifully shown by Dr. Frankland. He produced the mixed gases, in a darkened room, by means of the electrolysis of hydrochloric acid. The gaseous mixture was then passed into a small collodion balloon. Two parabolic reflectors were then arranged one over the other, the lower one being placed face upwards, and having in its focus the charcoal points of an electric lamp; by this means the light was sent vertically upwards in the form of a solid cylinder of rays against the upper reflector, upon which they were received and reflected downwards again to a focus, being concentrated to a point some five or six inches below the level of the upper cylinder. The hydrogen gas which was mixed with the chlorine in the balloon, was sufficient to give the whole a slight ascending power in the atmosphere. The balloon was then allowed to rise to the proper position below the upper reflector, when the concentrated beam of electric light fell upon the mixed gases and caused them to explode instantly with a violent detonation. That the effect was not due to heat was shown by the collodion envelope being unconsumed after the explosion, the torn shreds falling on to the floor. This experiment shows that light is to chlorine, to a certain extent, what heat is to oxygen.

A new process for preparing nitrate of silver has been recently published in several periodicals. It consists in dissolving impure silver in nitric acid, and when the liquid is almost neutral and cold adding a solution of sulphate of soda to precipitate the sulphate of silver, which is to be washed in distilled water; after this, digest it with the aid of heat in an equivalent proportion of nitrate of baryta, thus forming sulphate of baryta, which may be separated by filtration, and leaving nitrate of silver in solution which can then be crystallized. This is by no means a difficult process, but we do not think it would answer well in practice. The product could scarcely be pure. The facility with which nitrate of silver combines with alkaline nitrates, makes it likely that it would have a certain affinity for nitrate of baryta.

The specification of a very trivial photographic patent has just been published. The patentee, Mr. Mills, has not, however, proceeded with it; owing, no doubt, to the extreme want of originality which it displays. In order to give a more natural appearance to the sky of opaque. stereoscopic slides, which usually appear white, or nearly so, the inventor cuts away such portions of the pictures as represent sky, going very carefully up to the outline of the objects represented in the pictures. Then in viewing stereoscopic slides thus manufactured, he employs a stereoscope with an open or transparent stage, and allows light to pass through this stage, as is usual in viewing transparent stereoscopic slides. This light he colours by causing it to pass through a coloured medium, and in this manner he obtains, or supposes he obtains, the appearance of a transparent sky, either blue or of other tints which may be desired.

Examinations of glass for photographic purposes in the spectroscope are still being asked by our correspondents. Several have been received since we last reported on this subject. Below we give the results of our trial experiments.

18. T. W. S.—This specimen of glass is of a brown colour when viewed by transmitted light, and becoming much darker, when it is placed upon white paper. It is not coloured on the surface only, but is a body colour throughout. Tested in the spectroscope by diffused daylight, it was seen to cut off almost completely the blue, indigo and violet rays above the fixed line F. When, however, the instrument was directed to the sunlight considerable quantities of these rays, especially near the line F, were seen to be transmitted. This glass would therefore afford no security if the collodion were one containing bromine, and scarcely any if a pure iodised collodion were used. Two thicknesses of this glass would be nearly safe if sunlight were not allowed to shine on it, but the operations must not be conducted very near the window.

19. J. S. R.—A saffron coloured glass. This is almost identical in tint with the one described as No. 2. S, at p. 349, No. 151; if anything, a trifle darker. It would be no more efficacious than the one there mentioned.

20. F. N.—A dark red glass. This is very decided in its action on the rays of the spectrum. Most of the yellow, and all of the green, blue, indigo, violet, and higher rays are cut off very perfectly, even when the strong light of the sun is used. The transmitted light is almost pure red, being only fringed at the upper extremity with a narrow orange band, and is entirely without injurious action, whatever be the preparation of collodion which is sensitised behind it. The only objection is the great amount of luminous rays which it cuts off, which being without action on the sensitive plate, might just as well enter the photographer's room for the benefit of his eyes. This glass is similar in its properties to No. 9, p. 349, and like it is rather painful to the eyes after long examination owing to the green hue which it causes everything to be tinted with. This, however, is an objection which might disappear when the eyes become more accustomed to its employment.

A specimen of yellow oiled silk, and a few more pieces of glass which have been received too late for examination this week, will be reported upon in our next article.

SOME NOTES ON POSITIVE PRINTING.*

BY SAMUEL FRY.

From the preparation of paper and printing I come in turn to toning, which is often one of the most puzzling matters to an amateur or tyro, and even to a large number of professional photographers. I presume all now adopt what is known as alkaline toning, although the preparation should really be neutral or as nearly so as can be managed. Where this is the case, it will be found that over printing is scarcely necessary, or under most circumstances to a very slight degree, and this will be found to save much valuable time, as the excessive over printing required for very alkaline toning nearly doubles the time in the printing-frame. Where quantity is an object this may be of importance. But in addition to this, I am inclined to think that from a neutral solution may be obtained a larger variety of good tones than from the alkaline. Prints should certainly be toned as speedily as possible after removal from the frame, for during warm weather especially, the surface soon becomes horny, and difficult of penetration by fluids, as will be found by the length of time required to dissolve out the free nitrate of silver; this latter I generally expedite by a bath of weak salt and water after a few minutes in luke warm common water, by this method the whole of the silver is at once converted into chloride. Many photographers are careless about cutting the black edges of paper from their prints before toning; if this be not done, a serious loss of gold is involved. It is generally estimated that a grain of gold should tone a sheet of paper, but to make it do this it is essential that these edges be cut off, or the gold will scarcely tone half its quantity, this intense black of the outer part becoming toned almost instantly, whilst the print itself loses the gold thus consumed. The time required for the tone to be acquired must naturally vary with the strength of the silver bath, the character of the paper, and the temperature of the solution. With a silver bath of 60 or 65 grains, Rive paper, and the gold bath at a temperature of 65° Fahrenheit, if the gold be in the proportion of 1 grain to half a pint of water, a very few minutes will suffice to give the prints a fine colour. I differ from those who recommend a small number of prints only to be immersed at a time. W[illegible]

* Continued from p. 412.

this is done, there is danger of the first few absorbing too rapidly a large quantity of gold and becoming blue. I prefer to take a dry dish, and having the prints close at hand, in a vessel of luke warm water, place a print face uppermost on the bottom of the dish, and pour over back and front just sufficient gold solution to cover it, repeat this with all the batch, stopping occasionally to turn them over, by this means all patchiness of colour is avoided, each print has its proper quantity of gold, and a uniform tint will pervade the whole batch. By regulating the time of immersion almost any colour may be obtained, but the utmost care is needed to avoid too long an exposure to the influence of the gold, or the whites become degraded, and the whole tone of the picture needlessly lowered, a cold heavy gray taking the place of rich warm vigorous tones.

As the one great object sought in all the pains bestowed on our prints is to obtain rich, powerful pictures, reproducing as nearly as paper can do, all the vigour of the negative, our labours would be ill bestowed if, by any oversight in the final processes, the prints lost their beauty nevertheless it is a complaint of daily occurrence that this is the case; one obvious cause of loss of vigour and tone in the hypo is ommission of a thorough washing after toning and before fixing, if this be properly carried out, there will rarely be found the loss alluded to. The most potent cause of poor tones, mealiness, and weakness, is an insufficient strength of silver-bath. Every grain of silver has its part to play, not only during the actual exposure to daylight, under the negative, but in the producing every tone and shade, and during the colouration and fixing. I recommend a quarter of an hour in the fixing bath of new hypo, 4 ozs. to a pint of water, at the expiration of this time, the prints should exhibit perfect purity of white, and by transmitted light should be so transparent as to leave the fine fibre of the paper unclogged by opaque matter. Before immersion in any vessel of water to remove the hypo, each print should be placed on a sheet of glass, and well washed under a considerable force of water, which may be thus applied without fear of abrading the surface—this being done, if circumstances allow they should be all placed before going into the tanks in lukewarm water for half an hour, this having more effect in removing the hypo than a much longer period of cold water, and if properly toned and fixed, no apprehension need be entertained of losing the tones already acquired. Three or four hours after this in running water will be ample to remove all traces of hypo as may be easily ascertained by a test always at hand; thus, after hanging a print to drain until the drops fall very slowly, allow one drop to fall on to a piece of sensitized paper which is peculiarly sensitive to the presence of hypo, the smallest trace is sufficient to produce a brown stain; if none be present the prints may fairly be assumed to have had sufficient washing.

"CARTE DE VISITE" PORTRAITS.*

One of the most pleasing forms of photographic portraiture is the *Carte de Visite*. Fashion may have much to do with the great demand for this kind of picture, yet its inherent attractions together with its cheapness are sufficient to account for its great popularity.

The usual size of the cards upon which these portraits are mounted, is 4 by 2½ inches, the pictures being about a quarter of an inch smaller each way.

The distinguishing characteristic of these portraits is their including a full length. The position may be sitting or standing, but the feet must be introduced. This constitutes the charm of the picture, for the photograph is no longer a fragmentary representation of a half or three-quarter length, or the mere head, but comprises a complete portrait of the whole person. Thus a skilful artist may in these pictures produce more truthful likenesses by rendering accurately not only the features but also the proportions and form of the figure, together with many of those peculiarities of dress and deportment that constitute the idiosyncrasy of the individual. Great scope is also afforded for the introduction of appropriate accessories, drapery and backgrounds, so as to form not only accurate likenesses, but also pleasing pictures.

The position may be either sitting or standing, the latter being most usually selected as better displaying the form and proportion of the individual. It is here the true artist will shine in the selection of such arrangements and disposition as accords with the character of his sitter. No rules can be laid down but such as good taste and the exigencies of the moment, or the peculiarities of the individual, may suggest.

The primary object should be to produce a characteristic likeness, and the secondary one to render it as pleasing as possible by a judicious selection of the view of the face and *pose* of the figure, so as, without sacrificing character, to bring out the good points and conceal the less favourable ones. Much more scope is afforded in these "cards" than in the usual photographic portrait. In the latter, the main attention is concentrated on the head, the rest of the portrait being kept quiet and in repose. These small full-lengths allow more latitude, and should represent the person with something of the freedom and action of every-day life. Some photographers have but two or three positions in which to place their sitters; this, though bad enough in ordinary portraiture, is execrable in card pictures, where the object should be to introduce as much freedom and variety as possible. As no two persons are alike, so no two should be posed the same, and the accessories should be differently arranged in each case.

These little pictures permit the introduction of many graceful additions, which materially enhance pictorial effect. Drapery, balustrades, columns, pedestals, vases, handsome chairs and tables, footstools, couches, all find their appropriate places when arranged by the hand of taste. Painted backgrounds may be judiciously used, but they require care in their management to avoid theatrical effects and noisy display. They should always be quiet, retiring, and unobtrusive, and be in complete harmony with the portrait. Unless they are so used they had much better be abandoned, for by the use of other accessories they can always be dispensed with. Even in the use of these accessories considerable moderation is required not to bring too forward these subordinate parts of the picture. Nothing can be more unpleasing than to see a portrait of a person surrounded with a crowd of incongruous objects, and it becomes almost painful to see the same things monotonously repeated in the portraits of a number of friends.

As these portraits are so small it is important that the definition be very perfect. The quarter-plate lens with which they are generally attempted to be taken, is rarely equal to the task, the reason being that their fields have too much curvature, and the definition is seldom sufficiently good on the edges of the field. Hence many a lens that takes a good quarter-plate sitting picture where the head is near the centre of the plate, fails to give a well-defined card-portrait where the head and feet are placed at the edges of the field. This roundness of field is often advantageous in ordinary sitting pictures; but in the small full-lengths it is objectionable. It is very annoying in focussing on the hands to find the head and feet indistinct, and, on turning the lens to make the latter sharp, to find the former all blurred.

A lens, though possessing a curved field, if it give good definition on the edge of the field, may, by the use of Waterhouse diaphragms, be fitted for taking these pictures by employing a stop that causes the head, feet, and hands to be in focus at the same time. If a lens, however, does not give good definition on the edge of the field, no stops will enable it to take these portraits well, and the only remedy is to obtain a better lens. Taking a visiting-card

* From the new edition of "The Principles and Practice of Photography," by C. Jabez Hughes, noticed in another column.

taxes a lens much more than taking an ordinary quarter-plate portrait.

When the glass room is long enough, a half-plate lens is the proper one to use, and much less distortion, more natural proportion, and more equable definition will then be obtained. Lenses are now being made expressly for this kind of picture, the focal length not being much longer than the quarter-plate, but giving flatter fields, so that head, hands and feet, may be all sharp at once, without requiring a small stop.

In taking these pictures it is important that the lens and camera should be kept horizontal, and pointed nearly opposite the centre of the figure. Unless this be attended to, especially with short focus lenses, the individual will be represented as if standing on an inclined plane, instead of a solid floor; the lower part of the legs and feet will also be considerably distorted and out of focus.

These pictures require a special arrangement of light. They will bear a little stronger distribution of light and shadow than ordinary photographs, for as all the features are so small, it is important they be well marked. Sufficient diffused light must, however, be used to soften the shadows and prevent the pictures being hard in outline and black and white in tone.

The collodion used should be such that gives transparent shadows; the bath should be slightly acid, and the developer should have sufficient acid to keep the deep shadows free from deposit. All the chemicals, in fact, should be in such condition as to give clear, clean, and brilliant negatives.

It is usual to employ a camera with two or four lenses mounted on it, and thus to take two or four pictures with one exposure, and by means of a repeating movement in the dark side of the camera, double the number may be taken on one plate.

In all other respects, the production of these pictures is the same as the usual photographs, except, that as they are so much improved by the final rolling process, that operation should never be omitted.

Critical Notices.

THE PRINCIPLES AND PRACTICE OF PHOTOGRAPHY FULLY EXPLAINED, &c. By C. Jabez Hughes. Second Edition. London: published by the Author.

We noticed the first issue of this excellent little manual only a very few months since, and are happy to find that the demand has been so large as to require a second edition already. This circumstance has enabled the author to give a new value to his work by the addition of several extra chapters on subjects of great current interest. Amongst these are "Intensifying Processes," "Instantaneous Photography," "Improved Gold-Toning Process," and "Carté de Visité Portraits," the latter of which we have, by the author's permission, transferred to our columns in the present number. We once more cordially commend this as one of the most valuable instruction books for beginners, and reference books for advanced operators.

ECCLESIASTICAL ANTIQUITIES. A Series of Stereographs. Hereford Cathedral. By W. H. Warner.

The series of stereographs before us will be a treat to the ecclesialogist, and all interested in the architectural memorials of antiquity which abound in our cathedrals, the home study of which is strikingly aided by photography and the stereoscope. It has often been observed that the stereoscope enables a man to become an extensive traveller without leaving his own village. It does more, it familiarizes him with by-gone ages, when with a scene like the present before him his mind reverts to the periods to which the views belong.

Here is the Library in Hereford Cathedral. The ponderous and precious tomes, quartos and folios of manuscript, are all safely secured by chains, being too rare and too valuable to remain loosely in their shelves, to the temptation of borrowing students. Insensibly the mind reverts to an ante-Caxtonic period, and glances into the black lettered and illuminated records. Still backward, the "Norman arches in the Choir" bring the retrospective mind to the period of the conqueror. Still continuing its backward flight, "The Font" brings the wanderer to a period full of interesting associations, the time of Saxon England. The tombs and monuments, of baronets and bishops; the varied styles of architecture indicating their varied periods, are all aids in the stereoscope—which so truly renders the exact texture of the time-worn stones as compared with that of the various restorations, with every other characteristic detail,—to archæological researches in the study, which might otherwise require the personal examinations and travel of years. Mr. Warner has entered upon the production of these slides, manifestly with an appreciative interest in the subjects he was pourtraying, which will give great value to the series. As photographs they possess considerable merit, and that merit is considerably enhanced in the eyes of a photographer when he remembers the difficulties involved in these dimly-lighted interiors. The negatives from which the slides before us were produced required exposure, as we glean from the written information at the back of each, varying from forty seconds to thirty minutes. They were all developed with iron, and with very few exceptions sufficient density obtained without further intensifying.

A series of large pictures of the same subjects was, we understand, produced, but these we have not seen. We can, however, cordially recommend these slides as giving a very perfect conception of the interior of one of the oldest of the fine old cathedrals of this country, and as pre-eminently valuable to the ecclesialogist.

STEREOGRAPHS OF THE ISLE OF WIGHT, AND INSTANTANEOUS SEA PICTURES. By R. James, Junr. Published at Ryde.

The Isle of Wight, as all who have visited it know, presents some of the most lovely subjects which can be conceived, for the stereoscope, and we have amongst Mr. James's slides, some of the best selected amongst these lovely views; but we also have, we are bound to add, some that are rather tame and commonplace. One of the first things the landscape photographer should learn, is to exercise the art of selection; and one of the next things he should learn, is to have the courage to destroy every negative which lacks pictorial merit. When a photographer exercises this self denial, and only issues such pictures as are really good, he necessarily rapidly acquires a reputation; but if he issue good and bad indiscriminately, simply because he possesses the negatives, he leaves it doubtful whether he is really capable of distinguishing the good from the bad of his own productions. We wish for the sake of the art, and for the sake of the photographers who thus publish indiscriminately, that a more rigid self criticism and self sacrifice were exercised before publishing. It would pay better in the end, as well as increase the reputation of all practising it. Amongst Mr. James's views, for instance, there are some very excellent, well selected subjects, and some capital photography; but there are, as we have said, some subjects which are tame and uninteresting, and some which are imperfect photography. Some with stopped out skies, which are thus spoiled both as pictures and stereographs. Mr James in a modest and intelligent letter which accompanies his pictures, tells us that the greater part are on dry plates, and that the skies are not sufficiently perfect to print without stopping out. Very good: don't print them at all. Those which are perfect are quite sufficient to gain Mr. James some reputation, which the others will only tend to destroy. We make these remarks in all kindness, because many of the pictures are highly creditable.

To some extent the same remarks will apply to Mr. James's instantaneous pictures. More rigid self-criticism and self-sacrifice should have been exercised before publishing. We have some charming views on the Solent of sun and cloud, sea and shipping. The general tendency is to slight under-exposure, to thinness in the negatives, and, in some cases, to a want of perfect instantaniety. Some of the pictures are very charming for all that; but some possess these faults in a degree sufficiently marked to destroy their other beauties; and these it would have been well to reject. The negatives we are informed, were chiefly obtained about the hours of four in the morning, with sun-rise effects, and eight in the evening during sunset. Some of these, although a little under-exposed, have great pictorial beauty. There is one slide, "Day-break on the Solent, from Ryde Pier, No. 338," a perfect gem of suggestive beauty and solemn grandeur. Darkness is on the face of the waters; the whole expanse of the sky covered by one huge dark cloud, through a rift in which gleams a faint streak of light, the source of which is as yet unseen, but this gleam is manifestly the harbinger of approaching day. The picture is full of poetry, and reminds one of what Danby or Martin would have loved to paint. Some other of the pictures of sea, cloud, and shipping, are very interesting, and not ill done. Mr. James has, in some instance, like Wilson, pointed his camera in the face of the rising or setting sun, a daring experiment, very fine in result when successful, but rarely securing sufficient success to justify the daring. Here, as in some of Wilson's, the sun is surrounded by an immense halo, manifestly due to some imperfection in the mounting of the lens, the tube of which causes this halo by its reflection. Where such an immense stream of effulgence is reflected in the water as that produced by the setting sun, it is imperative that the exposure be absolutely instantaneous, as the slightest movement in the water, destroys the exquisitely and strongly marked light and shadow on which the liquidity and transparency of the waves entirely depend. The manipulation in these pictures appears to be good, and the selection in most cases happy; the lenses we are disposed to think are the chief sources of defect, some imperfection in rapidity, in definition, and in mounting, being apparent. The series has nevertheless many very fine pictures, and the price is so low that anyone buying a score may easily pick out half a dozen which would be cheap at the price of the whole.

Mr. James has also forwarded us a very fine large picture of the interior of his glass room which shows a very choice selection and arrangement of accessories, and forms a fine picture. It is a good specimen of what may be effected by iron development.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 4th September, 1861.

Professor Gerlach, of the University of Erlangen, has obtained some photographs of microscopic objects by a new method, which consists in taking the object itself as the negative image, and then taking a magnified positive of this image, and repeating the operation, alternately positive and negative, until an image is obtained of such a size as to present details of structure for exceeding in magnitude those obtainable by the most powerful microscopes at present in use.

On the other hand, Herr Fierlander announces that he has succeeded in obtaining by the assistance of an Oberhauser's microscope, photo-microscopic negatives of the most delicate organs of plants, and magnifying under very satisfactory conditions of success these infinitessimal negatives, so as to obtain positives comparable to the best phyto-glytic engravings. Although his positives are extremely good, we do not perceive in them any degree of merit superior to that possessed the productions of many other photographers, still, however, we are always glad to welcome every effort in extending the applications of photography.

M. Gaudin, in a new communication on the accidents occurring in the endeavour to obtain maximum sensibility, shows how mysterious and delicate are the agencies concurring to the successful production of a negative picture by the materials now in use, and places in a most striking light that condition of things so expressively denoted by Sir John Herschel as "a state of tottering equilibrium." M. Gaudin intimates that it is not his intention to publish the formula of his collodion-photogene, but to manufacture it for sale. In these days of subtle chemical analysis, we can hardly encourage the idea that he will be able to maintain the secret of the composition of his new agent.

Professor Zantedeschi, of Padua, asserts his claim to prior invention of the *spectroscope*. He states, that in 1852, he instructed M. Porro, the eminent optician of Paris, to make a spectroscope after a model with which he (the Professor) supplied him, and which is described in a memoir he published under the title of "*De mutationibus quæ contingunt in spectre solari fixo*," which was also inserted in the 8th vol. of the Memoirs of the Royal Academy of Sciences at Munich, for 1857.

Professor Zantedeschi maintains that his spectroscope is superior to that invented by Kirchoff and Bunsen. By means of an object lens, the rays enter and depart parallel with the prism, and consequently the phenomena of interference is completely eliminated; by means of another eyepiece, the spectrum can be projected on a plane surface, and analysed by several persons simultaneously.

In a memoir presented on the 13th of May last, to the Royal and Imperial Institute of Science, Art and Literature of Venice, the Professor contributed a paper entitled "*Critical and historical remarks upon the luminous spectrum considered as a* photodoscope *or the most delicate analyser known to Science.*" On page 79 occurs the following:—

"In concluding this chapter, I must remark that the solar spectrum is actually the most correct *Photodoscope* that can be imagined. Light, so to speak, undertakes to describe and represent carefully all the changes which take place either in the nature of the luminous body itself, or in the medium through which the latter is compelled to traverse. On that account I think it useful to suggest to physicists the construction of a camera intended exclusively for *photodoscopic* observations. Such observations will certainly yield most interesting results, not only for meteorology, but also for the science of light and for astronomy. Light, which to our eyes seems intended to paint the face of nature, is capable also of depicting itself in displaying to us new marvels proceeding from the secrets of its own nature, and in making known to us the changes our planetary system undergoes." Also, on p. 59:—"These very delicate and most interesting phenomena are the best that science has supplied us with for comparing together the lights proceeding from different sources, and estimating their reciprocal action upon matter which we designate *heavy*."

A specimen of paper manufactured from wood has lately been introduced to the notice of photographers. It is of perfectly homogeneous texture, free from spots, knots, and other objectionable defects; it seems admirably adapted to copper-plate printing, and equal in every respect to *India-paper*. Its price, too, is moderate; in fact, half the cost of paper made from rags. As it consists of pure cellulose, I hope that it will be found available for photographic purposes.

M. Cari-Montrand, has turned to industrial account the scientific fact, long since enounced, of the decomposition, under the influence of an elevated temperature, of dry phosphate of lime mixed with carbon, by means of hydrochloric acid, as a means of manufacturing phosphorus on a large scale.

Calcined bones, reduced to a fine powder, are mixed with a quantity of pulverised wood-charcoal sufficient to convert all the oxygen of the tri-basic phosphate of lime into oxide of carbon. The mixture is placed in cylinders of refractory clay, glazed on the interior, and fills about three-fourths of their capacity. These cylinders are made red hot, and then a current of hydrochloric acid is passed in at one extremity.

Under these circumstances the phosphate of lime is immediately decomposed, and chloride of calcium, oxide of calcium, hydrogen and free phosphorus are formed. This latter is distilled, and by means of a copper tube dipping into a vessel of cold water, it is condensed together with some oxide of carbon, hydrogen, and the excess of the hydrochloric acid gas. The water of the refrigerating condenser becomes very acid by the absorption of the excess of the hydrochloric acid gas, and is employed to digest the calcined bones, which are dissolved, or at least, softened in it, by which the trouble of pulverising them is avoided. The magma resulting from this maceration is mixed with the carbon, and the whole evaporated to dryness, and completely dessicated before being introduced into the cylinders.

The hydrochloric acid is obtained by the decomposition of sea-salt by sulphuric acid, and the chloride of calcium which forms the residue in the cylinders may also be turned to account, for, treated by sulphuric acid, the hydrochloric acid is regenerated, and sulphate of lime is formed, which is useful as a manure. The chloride of calcium may also be decomposed by steam.

THE ART CLAIMS OF PHOTOGRAPHY.

"Audi alteram partem."

Sir,—The old and trite story of the two-sided shield seems to illustrate, not inaptly, the controversy which has recently arisen regarding the position photography is to occupy in the International Exhibition of next year. Photographers, or at least some of them, have accustomed themselves to look only on the golden side of the shield, and appear ready to do battle with all comers who shall declare that any particle—not to say a whole side—of baser metal enters into its composition.

To a looker-on like myself, associated with art, but not indifferent to a power, so nearly allied to art as photography, and having some practical knowledge of both, the controversy, the record of which in your pages I have read, has alternately amused and surprised me. If it be not altogether "flat blasphemy," to do so in a photographic paper, I should like to submit, very briefly, one or two considerations regarding the art claims of photography, which seem to have escaped the attention of those who demand for it an unqualified and unquestioned position amongst the fine arts.

Is photography properly an art or a science? I shall doubtless be answered that it is both; and, to a certain extent it doubtless is so. But is it not more properly the latter than the former? Does it not depend from first to last for the production of results upon a series of chemical reactions? What is the tyro in photography first recommended to study in order to attain certainty and excellence in his operations? He is told that he must at the outset gain some knowledge of chemistry. To what does he chiefly attribute his failures when they occur? His "chemicals" are out of order. What are the topics chiefly discussed at meetings of photographers? So far as I can glean they are chiefly "chemical conditions," "processes," "modes of manipulation," "powers of lenses," &c. Who are the men who chiefly take part in these discussions and appear to be leaders? Chiefly chemists and men of science. Who are the "professors" of photography in the only college where a faculty of photography exists? In King's College the late professor was an eminent chemist, and the present professor is, I understand, chiefly eminent as a mathematician, and a student of general science. Upon what does the professional photographer generally rely for success? Upon the purity of his chemicals, the perfection of his lenses, and upon, as you recently pointed out the phrase, his skill as an "operator."

I am not anxious, sir, to search far for these evidences of the essentially scientific character of photography. These evidences all lie on the very surface, and present themselves first to impartial observers. If I am not mistaken, this view of the matter was, until recently, that entertained by photographers themselves; and I think I remember to have seen quoted some remarks of a distinguished member of the photographic society's council, to the effect that he did not see what was wanted with "pictures" in connection with the *science* of photography.

But I shall be told that whilst photography is based upon science, and requires a strict regard to certain principles of chemistry in practice, yet in result it is essentially a fine art. "If," says one, "photography be merely a process consisting of a series of definite chemical manipulations, then the results would, *cæteris paribus*, be of equal value in each manipulator's hands." Another insists that "photography can embody pictorially all that is beautiful in nature or art; that everything of beauty the eye can see, photography can depict; and therefore it is a fine art." Another advocate exclaims that "photography is capable of expressing intention and design, and is therefore a fine art." The president of the Photographic Society in his first letter to Her Majesty's Commissioners, observes that it "gives room for the exercise of individual genius, so as to stamp a special character on the works of photographers, and give to the result of their labours the impress of the mind of each artist."

All these arguments may have some value; but they are not sufficient to prove that photography is a fine art. To the first argument that if photography were a mere process all its results would be the same, it is merely necessary to observe that there are differences in the amount of skill shown, and results produced, in the most mechanical arts. The crossing-sweeper observed that sweeping a plain pathway was simple enough, but to produce a neat curve or sweep round a corner, "that was fancy-work."

With all due deference to the second argument, I must affirm that the mere pictorial reproduction of the beautiful in nature and art, even if all affirmed were true, does not constitute a legitimate claim to a position in the Fine Arts. Photography has not yet attained the power of depicting all that is beautiful in the world of beauty; even some charms besides colour have as yet eluded its powers. But without depreciating its wondrous results, I must submit that they form no necessary claim to the position demanded. The reflected presentment of a fine landscape in a mirror, is as lovely a picture as can be conceived; not merely form is there, but colour in all its ever-changing beauty; golden sun-light and transparent purple shadow; and atmosphere with all its indescribable charms. All this is in the mirror, and the picture is matchless in truth and beauty. But is the mirror-maker an artist, or is silvering looking-glasses a fine art? Or would it be any more so if the power existed to fix, by some chemical process, these mirrored beauties? They are reflected there by the operation of one law of science, and they might possibly be fixed there by another. But there is a mighty difference in method and result between these, and the visions of beauty drank in from nature, and pondered and recombined by the conceptive brain of the artist, and reproduced on the glowing canvas by his trained hand following the impulses of that brain, and not working out a chemical process. Again, if the production or reproduction of pictorial results by mechanical means gave the respective methods employed, art claims, the workmen on the *Gobelin* tapestries, and the printers of chromo-lithographs would be artists. Having admitted these claims, stencillers and carpet weavers would surely point to their pictorial efforts; and where should we stop short of Berlin wool work and sampler embroidery? In all these, too, as well as in higher and lower branches of the mechanical arts, it is quite possible for the mind of the workman to impress itself upon his work, and give especial character to his results. Emphatically I exclaim that photography is not *per se* a Fine Art.

Thus far and briefly on the claims of the art. A few words now on the claims of the artists and their productions. Let me ask you, sir, is there one per cent. of those practising photography who have any claim what ever to the name artist? or who have had any art training or education? There are a few names I know, eminent amongst photographers, who also have had previous training and experience as artists; there are such men as Lake Price, and Rejlander, and Wilson, and Delamotte, and there may be others. But these are unquestionably the exception; not the rule. For the most part those claiming the name of "photographic artist" have left "the farm and the merchandise"—if I may include under this euphemism many less dignified callings—to take up the camera. Amongst these I willingly admit the existence of many men of eminently artistic capacity and taste; but these again are the exception, not the rule. Then as to the results of the art, how many libels on the "human face divine" has it not been guilty of! Fine art! Why photographic portraiture has been the very apotheosis of the common-place and vulgar!

And now I fancy some enthusiastic photographer ready to exclaim, "Why the fellow who can form his estimate of the capabilities of our glorious art by an examination of the specimen cases of twopence-halfpenny portrait shops, is unworthy of attention. Why does the fellow ignore the exquisite productions of Mudd and Bedford, Heath and Wilson, Rejlander and Williams! Why I wonder if the fellow ever saw a good photograph!" Fair and softly my extravagant young friend. I have a portfolio of photographs in which are specimens of the masters you have named and some others, and which I cherish amongst my art treasures. Nay more, I unhesitatingly admit, that I have seen many photographs perfect gems of art, and that photography in the hands of a true artist may often yield results worthy to be classed as works of fine art. But all this is due to the man, not to the method. The true artist will make himself felt no matter what the vehicle of expression. I have seen evidences of artistic skill in the drawings in coloured chalk on the pavement by a mendicant, and in the design scratched with a rusty nail on a pewter plate by a prisoner. But I should not call the processes by which these results were obtained fine arts. I do not use these comparisons in any derogatory or offensive sense; but I cannot but come to the conclusion that in the present state of photography the acknowledged chemical skill required, and attention to other scientific conditions is absolutely a clog upon the artist. I have heard photographers exclaim as they examined some glorious conception of an art-photographer, with a purpose and intention suggestive of beauty in every line, "What a pity he is not a better photographer?" The art was good but the photography was imperfect. And yet the men who would pooh pooh such pictures, will claim for photography the rank of a Fine Art!

I have purposely avoided any remarks on the fact that photography must be literal. It cannot, except in a limited sense, select; it cannot combine; it cannot modify; it cannot idealize; it cannot imagine; it cannot create. Whatever comes within the range of the lens, beauty and ugliness alike, all are uncompromisingly depicted. It is not always true, or even near truth; but commits some most contradictory blunders. Yellow, the colour which on the palette is most allied to light, it represents by darkness. Blue, which the painter regards as most allied to shade, it renders by its nearest approach to light. I am willing, for the present, however, to bate these considerations.

If I have not entirely exhausted your patience, I should like to add one or two remarks on the position assumed by the Photographic Society towards Her Majesty's Commissioners.

In the classification first issued, photography, probably from some scarcely considered following of the catalogue of 1851, appeared in the mechanical department. When the attention of the Commissioners was called to the matter, they at once expressed their wish to do all honour to the art-science, and stated their willingness to give it a room to itself, where the photography of the world might be displayed. What more desirable concession could be hoped for I cannot conceive. The Commissioners do more: they ask the Society to appoint a committee to co-operate with them, and by that act at once intimate a desire to make such arrangements as may be most palateable to photographers, and just to their art. But no; the old proverb must be illustrated: *Quos Deus vult perdere dementat prius.* The Society, already tottering to its fall, might have gained new strength and life from an active alliance with the great international undertaking, declines the chance. Her Majesty's Commissioners are an insignificant and unimportant body: the Society is a big and powerful body, and it must dictate terms. The Commissioners must eat humble-pie, and, publicly, at the bidding of the Photographic Society, confess to a blunder. It shows a fine knowledge of human nature, and we know the result.

To complete the joke, and at least keep it consistent in all its parts, the society recommend photographers generally to abstain from exhibiting. Here is a chance for them to show there productions to how many hundreds of thousands of persons, shall I say—may I not say millions?—from all parts of the world; and on some fancied construction as to dignity—which no man in his senses can conceive to be an intentional slight on the part of the Royal Commissioners to an art practised by royalty or a society patronized by royalty—they are to refrain from such a chance of publicity! This is another fine example of the knowledge of human nature, and we shall see the result.

Apologising for this long intrusion into your columns, which without pleading the force of the motto which heads my letter I could not have dared to attempt.—I am, sir, your obedient servant, R. A.

[Admitting the force of the motto named, we insert the communication of our correspondent. Next week we shall probably have a few remarks to make on the subject.—ED.]

"ANSWERS TO CORRESPONDENTS."

SIR,—Recently in a photographic contemporary uncomplimentary doubts were expressed as to the genuineness of this interesting and valuable portion of photographic journals. The person who wrote the remarks must either have a very limited circle of dull correspondents who never desire information or very self-satisfied ones, who need ask no questions. For my own part, I remember the time when I used to rush eagerly to this column to get some new "dodge," some fresh "wrinkle," some stray hint, and which was oftener of far more value to me than the heavy optical papers crammed with hieroglyphics, or dry-as-dust chemical ones, bristling with symbols and formulæ which occupied the bulk of the journal. At that period I read my journals, as Jews read Hebrew, backwards, beginning at the last page. I am not certain that I have quite discontinued the practice yet. I am sorry, therefore, that anything should be said likely to throw doubt on this desirable portion of photographic journalism. Because a man, residing in an obscure, out-of-the-way place, have few persons passing his door, is he to deny the existence of crowded thoroughfares? and, if Mr. Briefless have no cases, are Serjeant Bluebag's all myth's? Suppose a man live in the Hebrides, can he expect as many correspondents as by residing in Cheapside? The Scilly Islands are not remarkable for their amount of postal communications. When a man gets a correspondent, a good deal depends on how he answers him, whether he or his friend apply again. In former days I wrote many times for information, and frequently received useful hints, for which I was very thankful at the time, and have experienced a lively remembrance of ever since. I'll admit I did not write to Shetland or Kamschatka. If a photographic journal had existed in Nova Zembla or Patagonia, I think I should have preferred sending my communications to London.

Having, therefore, availed myself of the information of editors in their "answers to correspondents," I do not care to have my corporeality doubted, and my existence denied. My mythical character will be assumed soon enough, but not for a good few years yet I hope. Neither do I like gentlemen's veracity to be impeached for kindly answering my inquiries. I fully believe your answers are all genuine, for many of the questions, from their inherent foolishness, could certainly not emanate from your own brain, and the rest would naturally come from sensible readers.

I do not think that a person is bound to sign his own name when he asks for information. When John Smith asks why his collodion film peels off his plate on drying, or Henry Brown what he is to do with his bath that he has dropped a bit of hypo into. what does it matter how these persons sign thsmselves? When I once wrote I subscribed myself a "Photo in a Fix," and so I was. Another time I was "In a Fog," and the worst of the matter. it was true. With the "Correspondents," therefore, I have great sympathy. "A fellow feeling makes us wondrous kind." It is bad enough for a poor fellow to have to confess his troubles; pray don't compel him to publicly give his real name and address too.

But my idea of this "Answers to Correspondents" column is, that it should contain nothing but such that is interesting to the body of the readers. No portion should contain answers to private or uninteresting letters; and the replies should be so stated as to be instructive not only to the individual correspondent, but to the subscribers generally. I especially object to having to buy and pay for answers to letters that I don't know the meaning of. A. B. may be informed that "the process you allude to is a very good one;" but why should not I as well as he know what process is described as "a very good one." Y. Z. is told, "your lens is too long in the focus;" what is it too long in the focus for I want to know? This sort of answer is tantalising, and is, moreover, unjust to the great bulk of the readers. Why should one, two, or more lines be inserted which is interesting only to one reader. The plan you adopt in the News is a great improvement, where you either state the question, or so word the answer that the same information is made useful to all your readers. I dare say correspondents often ask foolish and irrelevant questions; but editors should not punish their readers by inserting equally uninteresting and irrelevant replies. Some of the answers read as mysterious as the second column of the *Times* advertisements. I sometimes read, "Yes, we have our eye on the individual. and shall catch him when he least expects it." Am I to understand by this and similar replies that there is a corps of photographic detectives going about seeking whom they may devour? I object strongly to this inuendo and semi-confidential style. Whispering in company is notoriously bad manners; but whispering in print must be a breach of all etiquette. If the letters are not worth an intelligent reply, let them remain unanswered; but don't make this column a "poste restante" for everybody who writes to the Editor.

Interesting as it is now, I am certain that well managed "Answers to Correspondents," might be made one of the most useful features of your paper, for the question made by one, has doubtless been *thought* by a hundred, so in answering the one, you do the same to ninety-nine others, as well as informing many more to whom the question may not have occured at all.—Yours, A Live Correspondent.

[The remarks in a contemporary,—who was, we fancy, joking—as to correspondents generally being myths, amused us. It sometimes taxes our ingenuity to supply satisfactory answers to all the questions we are asked—ranging, with every gradation, between the manufacture of telescopes and the mending of mangles—without perplexing our brain with the invention of difficulties. It is our aim always in answering one correspondent, to make the information intelligible and useful to many.—Ed.]

Dictionary of Photography.*

Refraction.—So long as a ray of light passes through a transparent medium of the same degree of density, it proceeds in a straight line without any deviation. But the moment the density of the medium is changed, the ray of light, entering at any angle but a right angle, is bent or turned aside a little in its course, or, in other words, it suffers refraction. If it enter the new medium perpendicularly it continues the same straight course, but if it enter at the slightest angle refraction ensues. A very simple and familiar example illustrates this. If a stick be plunged into water obliquely it appears to be bent at the point of contact with the water. The amount and direction of the refraction is determined by the variation in the respective densities of the mediums through which the ray of light passes. When the ray of light passes from a rarer into a denser medium, as from the atmosphere into water, its direction is bent towards a line passing perpendicularly through that medium; and when it passes from a denser medium into one more rarefied, it suffers deviation in a direction from a similar perpendicular. As a ray entering a piece of glass from the atmosphere would be refracted towards the perpendicular, so it would, of course, on leaving the glass and passing into the atmosphere again, be refracted from the perpenicular, resuming the direction it had before entering the glass.

The angle formed by the incident ray at the point of incideuce with the perpendicular, is called the *angle of incidence;* and the angle formed with the perpendicular by the same ray, after being bent, is called the *angle of refraction*, and the sines of the angles of incidence and refraction are always in the same ratio.

It is in virtue of this law of refraction that lenses can be made to refract light in any desired direction, Since light in passing from the atmosphere into glass is always refracted or bent towards a line perpendicular to the surface at the point of incidence, by varying the form of the surface, the direction in which the light shall be bent or refracted can be determined and regulated.

Various transparent bodies have different refractive powers, generally dependent on their density, but is also much regulated by their chemical character, all inflammable bodies refracting light much more than non-inflammable bodies.

Reproduction.—A term used by the French, and from them coming much into use amongst English photographers, intended to indicate what is sometimes technically called copying. A reproduction is a copy from another picture, whether the original be photograph, painting, or engraving.

Resins.—Vegetable substances obtained from the exudations from various plants and trees, which are generally discharged in a fluid form, and subsequently become concrete. They are frequently at first combined with some volatile or essential oil, and are then known as *balsams*, a common example of which, considerably used in different departments of photography, is the balsam of fir, or Canada balsam. Resins are of various colours. generally more or less transparent. somewhat brittle, having a smooth conchoidal fraction. They melt with heat, and are mostly inflammable, burning with a dense flame, and emitting a more or less aromatic odour.

They are insoluble in water, but either entirely or partially soluble in essential oils, ether, alcohol, and the various hydrocarbons. Some acids, strong alkaline solutions, and fixed oils, have also the property of dissolving many resins.

Fossil resins, such as amber, are supposed to be the remains of antidiluvian plants. Gum resins, such as myrrh and aloes, are natural combinations of gums and resins, and are partially soluble, both in water and alcohol.

Resins are chiefly valuable to the photographer from their

* Continued from p. 417.

use in varnishes, and are valuable in proportions as they are transparent, hard, and tough, free at once from tackiness and pliability. Those chiefly used are lac, amber, sandarach, copal, animi, benzoin, dammar, and mastic. Some of these are wholly, and others partially, soluble in alcohol, essential oils and camphor being frequently added to assist their solubility. Those least soluble in alcohol are generally entirely soluble in chloroform or benzole. Those soluble in alcohol form varnishes, which generally require the aid of heat to enable them to dry bright and transparent; whilst those soluble in chloroform and benzole dry without the aid of heat, without showing any tendency to "bloom" or "chill." Amongst those used with the latter solvents are amber and dammar, and sometimes animi and copal. The resins chiefly used in spirit varnishes are lac and sandarach. The layer of resin left by spirit varnishes is generally less tacky, and less friable than that given by other varnishes, and is therefore most used for protecting negatives.

Common resin, or colophony, is not sufficiently hard for varnish purposes, but has been suggested for use in photography, as an addition to collodion for the preparation of dry plates.

Resin Process, The.—The use of resin in collodion for dry plates was originally proposed by the Abbé Despratz, and adopted since with various modifications, and in many cases with considerable success, by various experimentalists. Several resins have been tried, but that most usually adopted has been the product of the pine or fir-tree, either in the form of Canada balsam, or common colophony. The proportions used have varied largely, but those best suited to the production of good results appear to vary in different hands, from one-fourth of a grain to a grain per ounce. The supposed operation of the resin is to prevent the complete closing or contraction of the pores of the collodion in dessication. The plates are excited in a 40-grain nitrate bath slightly acid, and, after thorough washing, are dried without the application of any preservative preparation whatever. For the purpose of ensuring the entire absence of all free nitrate, the plates may, after washing in distilled water, be placed in a bath of salt and water, and then again well washed; or they may be washed well with common water, containing chlorides, &c. The exposure is said to be about half that usually required by a Fothergill plate. The development may be effected either by means of protosulphate of iron, or by pyrogallic acid. It is urged by many who practise this process as a point of great importance both as regards the shortness of the exposure necessary, and as regards brilliancy of result, that the plate be immersed in the nitrate bath for about one minute previous to the application of the developer. It is a point of importance to add, as regards the nitrate bath, that it should be acidified with acetic acid, and contain no trace whatever of nitric acid. About three or four minims of glacial acetic acid to each ounce of silver solution has been found to give good results. The chief difficulties to be anticipated are generally fog and blackening of the plate. This is caused by an unsuitable condition of the nitrate bath, probably from the presence of free nitric acid. Insensitive spots; these proceed from the presence of too large a proportion of resin. Splitting of the film, &c.; this is caused by the use of damp or dirty glasses, and by the collodion being too contractile. Want of density; this is chiefly caused by the use of an unsuitable collodion. To obtain the best results it is necessary to use a collodion giving a dense image when used wet, and without too large a proportion of bromide. It has been suggested by some experimentalists that as the best results are generally produced by the smallest proportion of resin, one-fourth of a grain being the amount recommended by some of the most successful practisers of the process, the results would probably be just the same, under similar conditions, if no resin at all were used; and that the introduction of a body insoluble in water, and inert on nitrate of silver, would simply be without operation in small quantities, and injurious in large proportions. A careful comparison of the operation of the same collodion under the same conditions, with and without the addition of resin, would be interesting in relation to this subject.

Photographic Notes and Queries.

Stereo-Exchange Club.

Sir,—In recent numbers of the News I have noticed propositions from two correspondents for altering the rules of the Stereo-Exchange Club. Either plan would, I think, if adopted, be a great improvement on the present system. As a proof that some change is needed, I enclose prints received in exchange for two of average merit. They were accompanied by an apology, certainly; but the amount of apology that could render such rubbish worth mounting would just about equal the impudence that could send them.

Of the two, "Stereo's" plan appears to me the most practical, and likely to be carried out to the satisfaction of members, most of whom, if I mistake not, would not desire to receive "similar subjects" to those they send, but would look upon the club as a means of varying their collections. Little onus would rest upon any good photographer who should undertake to class prints merely according to their merit as photographs; but he would sometimes find it difficult to satisfy members as to the value of the subjects he had selected for them, whilst, if this was left to themselves, they would have no room for complaint.

It only requires that some one should take the initiative in one way or other. If yourself, or any one you should name, would kindly undertake to act as secretary and publish the rules by which you would be guided in the News, I believe you would receive stereograms from as many photographers as would reorganise the club at once, and you would at the same time confer a great benefit on the contributors.—I am yours, &c., Binocular.

[A recent correspondent, whom we know to be well qualified for the duties, volunteered to undertake the duties of secretary under the arrangement he proposed. We only wait for more general assurance, on the part of members, that the new plan would be acceptable, in order at once to take steps to put it into practice.—Ed.]

Albumenizing Paper on Both Sides.

Sir,—Will you allow me to suggest the use of paper albumenized on both sides for printing positives; by this treatment the curling of the paper, a great annoyance, is entirely done away with, and the whole of the process made much more pleasant.

From experiment, I believe that greater permanence will be obtained, the paper should be of a close texture, and well albumenized on both sides, the sensitizing bath not less than 90 grains silver to the ounce; the paper to be immersed in it for one minute *not floated*. Photographs printed on this paper may be used for book illustration as there is no necessity for mounting them, which has been a great drawback to their use for this purpose, and prints mounted for portfolios, &c. are not half so curled up as may be frequently seen if the mount be thin. I remain, yours respectfully, R. Harmer.

The Spoon Plate-Holder.

Dear Sir,—In the description of my plate-holder in the News of last week two typographical errors occur, which I should not have troubled you to notice, were it not that one of them renders my meaning somewhat obscure. In the first place for *ribbet* read *rabbet*, next, for *drain* read *drum*. I may perhaps be allowed to add that to use this Plate-holder to the greatest advantage it should, after exposure, be applied to the glass plate as it lies in the dark slide on the removal of the lid. It will then safely lift the glass from the slide, and hold it securely through all the subsequent operations. I remain, yours truly, M. A.

To Gelatinise Plates.

Sir,—I pour the gelatine prepared as Major Russell directs, and pour it into a flat dish. I then affix the plate-holder to the back of the plate, and place the front gently on the solution. You thus get easily a very equal and regular covering of gelatine with the greatest ease. I have a Flavel's kitchen range, and I place a piece of blotting paper on the range, and allow the gelatinised surface to be towards the warm iron sides of the range. The draining is absorbed by the blotting paper, and the plates dry with the most satisfactory result, and many can be completed in a very short space of time. T. F.

Talk in the Studio.

The Photographic News Office.—Our readers have had a very narrow escape of being deprived of this week's Photographic News. An immense and alarming fire commencing in London House Yard, and extending into Paternoster Row, devastating a large amount of property, occurred the night before we went to press. The buildings immediately opposite our office were entirely destroyed; and as the Row is but a very few yards across, the flames repeatedly caught our windows, being only prevented from obtaining entire hold of the building by the continued efforts of the firemen. At the earlier stages of the fire, the wind being from the south, the flames rapidly travelled in our direction, and had no change occurred in the wind, nothing could have saved our own office and other buildings in the north side of the Row. Happily the wind changed in time, and we suffered little damage save cracked glass and some scorched "copy." The large tallow warehouse so long a nuisance in this spot long sacred to literature, is entirely destroyed, and happily will not be rebuilt.

Light, Heat, and Electricity.—Late investigations have shown that light, heat, and electricity, are convertible one into the other; that each may be measured by either of the others, or by the force of gravity. The mechanical value of the heat required to raise 1 lb. of water 1° is 772 foot lbs. Thus, light might be made to drive a clock!

Water Barometer.—Mr. Glaisher communicates to the *Times* an interesting account of the removal, under his superintendence, of the Water Barometer of the Royal Society from their apartments at Somerset House, to the Crystal Palace, where it is now erected and in operation. "The instrument is in an angle of the Tropical department, and near the great tree. The top of the column of water can be seen from the first gallery, and, as that which causes a variation of an inch of mercury, will cause a variation of more than a foot in the column of water, so the change in the latter will be more than twelve times as great as that in the former. Many oscillations, therefore, may be seen by the water which cannot be seen by the mercurial barometer; and in gales of wind or heavy storms, it will be highly interesting to watch its action.

Napthalizing Gas.—Our readers will remember that we described some time ago the great increase in both the illuminating and actinic power of the light from coal gas when the gas had passed through the vapour of naptha. We see it is stated that M. Leveque, of Paris, France, has invented a new apparatus for carburetting or naphthalizing gas. By its peculiar construction, the hydro-carbon liquid is kept at a constant height in the apparatus We understand also that a company has recently been formed in this country for the purpose of commercially utilizing the valuable qualities thus conferred on gas.

Novel Application of Photography.—In a report of a Committee of the House of Lords recently issued, upon the manner of fulfilling the conditions of the Turner bequest to the nation, there are some interesting remarks on the preservation of pictures. In referring to the influence of gas, it is stated that in order to observe accurately whether there was any increase in the number or extent of the cracks in valuable pictures, photographs of these cracks had been taken, thus preserving an unerring record of their condition in this respect at a given date.

Phenomena and Laws of Light.—Messrs. Elliott, Brothers, are now manufacturing an apparatus for illustrating the phenomena of the diffraction and interference of light. This is attained by the assistance of photography. Transparent apertures in an opaque collodion film are produced on glass, and a point of light is viewed through the apertures. The forms of the apertures are exceedingly various—triangles, squares, circles, ellipsis, parabolas, hyperbolas, and combinations of them, besides many figures of fanciful forms, are included in the present set. When an image of the sun is viewed through these apertures, figures of extraordinary beauty both of form and colour, are produced; and of each of these many variations may be obtained by placing the eye-glass of the telescope at distances from the object glass. Many of the figures produced, especially when the telescope is out of focus, might suggest very useful hints to those concerned in designing patterns. Although the phenomena are chiefly of interest to the student of science, in consequence of their bearing on theories of light, yet their beauty and variety render them amusing to all.

To Correspondents.

Clericus.—The brown mottled effect in your prints is the result of imperfect fixation. The strength of hypo you use, one ounce in six of water, is scarcely strong enough to begin with, and will soon get exhausted; hyposulphite of silver will be formed, but the solution will not be strong enough to dissolve it. The hyposulphite of silver decomposes, and causes the brown mottled spots of which you complain. The reason why it occurs sometimes and not always, is because the conditions are not always present. Thick, hard, highly albumenized paper will be more likely to bring about the result than thin absorbent paper. The sheets sticking together in the hypo will aid in producing it, and, of course, the solution being overcharged with the salts of silver from use. Make your hypo stronger, one ounce in four of water, and be careful to avoid the causes we have indicated.

James J. Maginn.—Various methods of taking several pictures on one plate with one lens, have recently been proposed. Your method seems to answer very well, and we shall be glad to receive the particulars. We should recommend you to think twice, however, and ascertain what has been done in that direction, before you go to the expence of procuring a patent.

H. Larriston.—See answer to Clericus. It is very important in fixing a number of prints together to keep them moving whilst they are in the hypo, and prevent them sticking together. Five minutes are scarcely sufficient time for fixation. Ten minutes or a quarter of an hour would be better. 2. Over-exposure would not necessarily render a negative slow in printing, unless it were over-developed as well. Read the article on "Iron Negatives" in our last. The negatives there described print most rapidly.

J. G. L.—The toning formula best suited to the production of good results with iron negatives is that in which acetate of soda is added to the chloride of gold; see "Notes of Positive Printing," by Mr. Fry, in the present number. We hope to have the experience of one or two other skillful photographers in this direction shortly. 2. A warm solution of common washing soda, and final rinsing, will render oil flasks chemically clean.

William Weston, Minor.—Powder colours for positives are prepared in various ways by different manufacturers, but they require skill and practice in such matters to succeed. Try grinding them very carefully with a little Canada balsam. 2. We do not know any photographic purpose, to which you can, with advantage, and without much expense, put a non-achromatic lens of six feet focus. 3. An amalgam of tin and quicksilver is used for silvering looking glasses; but we cannot direct you as to the method of proceeding; we do not imagine you will succeed as an amateur. 4 & 5. We cannot give you any practical information as to transferring lithographs to glass, or painting magic lantern slides. 6. The interiors of coal pits and stone quarries might possibly be taken by means of Moule's Photogen.

A. Miller.—We cannot recommend the collodion of any special maker. Any good bromo-iodized collodion is suitable for iron development. See our article on "Iron Negatives" last week. 2. There are enamelled iron plates for positives, which may be had of most of the London dealers.

E. P.—Bromide of ammonium is to be had ready prepared of all photographic chemists. The maker No. 2 we prefer. Instantaneous pictures are most frequently produced by stereoscopic lenses, but larger instantaneous pictures may be produced by quick-acting large lenses.

X. X.—You are using too much alcohol in your developer, a drachm to the ounce is a great excess. 20 drops to an ounce of developer is under most circumstances sufficient. Never use more than is necessary to make the developer flow freely over the plate. When the nitrate bath is new, scarcely any alcohol will be required in the developer. You cannot do better than purchase the lenses and apparatus you name. They are not dear for the quality of the apparatus. If you desire it, you may purchase a cheaper camera and use with the same lenses, without serious disadvantage.

J. C.—We are obliged by your communication, which shall appear in our next. The portrait is very fine, and the group, although a little unexposed, possesses much merit as a composition. The only fault in either arises from a little falling off in the defining power of the lens towards the corners. The gentleman you name has not been for some time past the editor of the News, but is one of its regular contributors. We do not think any portrait is published, but will enquire.

J. S.—It is impossible to focus satisfactorily with a coarse ground-glass screen. But you cannot grey the glass properly for permanent use yourself. Most dealers in photographic glass keep the fine greyed glass for the purpose. We have procured it sometimes of Claudet & Houghton. Hyposulphite of soda being very cheap, and the result so important, it is better to reject it when there is any doubt of its b ing out of order.

T. W. S.—You will find the report upon your glass in the proper place. To photograph polished silver goods place them in a soft light, use bromo-iodized collodion, expose fully, and develop with iron.

J. G. L.—We received some queries with this signature this week, which are answered above. We do not remember receiving such a letter a few weeks ago, nor have we received any query which relates to the "Journal of the Photographic Society."

F. L.—Scotch glue will answer for mounting if you use care. Starch should be made fresh this hot weather, as it turns acid in a few days.

Thos. Rogers.—The prints enclosed are imperfectly fixed. Use stronger hypo, and use more care to secure perfect fixation. See answer to Clericus. If you use sufficiently strong new hypo, keep the prints moving about, and leave them a sufficient time in the fixing solution, you will have no further difficulties of this kind.

James.—Black varnish should not be used to alabastrine pictures. Use dark velvet instead.

All Letters, Works for Review, and other Communications for the Editor, should be addressed to 32, Paternoster-Row.

⁂ Our Correspondents will aid us in our endeavours to solve their difficulties if they will in all cases state details of their operations when failures occur; and when referring to former articles in the News giving the exact reference. Letters intended for the Editor should be addressed expressly to him.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 158.—*September* 13, 1861.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

It appears to be admitted by universal consent that the annual meeting of the British Association, just held at Manchester, has been one of the most interesting and brilliant of the meetings which have been held since the Association was inaugurated thirty-one years ago. All the vast resurecs of accommodation and space which the manufacturing metropolis of the North possesses, was taxed to the uttermost, so large was the accession of members and associates, now numbering, we believe, upwards of 3,000. The magnificent Free Trade Hall was, on several of the soirees filled to over-flowing with a most brilliant assembly.

There is, to our mind, something especially satisfactory in the annual gatherings of an association of this kind, for the purpose of recounting, discussing, and summing up, as it were, the scientific progress of the year. True this is done from week to week, and month to month, in the press; but there is an inspiration derived from these personal meetings which cannot be too highly estimated. Renewed interest and impetus is imparted to the research in every branch of science, by the attrition of mind with mind, and the sympathy engendered amongst the explorers themselves, whilst an immense and beneficial influence is exercised upon the public mind thus brought into contact with the seductive charms of sciencitic inquiry, which in many instances, for the first time, discovers with Milton, that science is "not harsh and crabbed as some dull fools suppose," but a pursuit as solacing and delightful as it is elevating. Of course these meetings include a good deal of talking and dining. What is done in England without these? Talking is an important auxiliary to doing, and dining together is a process wonderfully promotive of harmonious co-operation. "At such meetings," it has been remarked, "men compare notes, get rid of the nonsense that obstructs great intents, and accelerate a clear understanding with each other. And such gatherings bring into play other great auxiliaries of progress—the dining-room and the drawing-room—where conversation, specially stimulated and concentrated upon definite subjects, gets over the ground splendidly."

The noble inaugural address of the president, Mr. Fairbairn, presents a most triumphant resumé, not only of the progress of science during late years, but also of its sound and practical character, and its immense influence on the daily well-being of mankind. In the constant advances towards a more perfect, and altogether higher knowledge of what, until very recently, have been amongst the sealed arcana of the universe,—photography has played a not unimportant part. If its position in the arts is doubtful, its value as the unerring recorder of facts in science cannot be disputed, and has received graceful recognition on several occasions during the proceedings of the association. Its aids in the progress of solar science, and astronomy generally, especially in the records of the late solar eclipse, are admitted facts of the highest value. Its records of magnetic and atmospheric perturbations are such as could not be obtained by any other means, and their importance cannot be too highly estimated.

The directly photographic contributions in the sections were not very numerous; but there was much matter nevertheless of direct and incidental interest to photographers, selections or abstracts from which we shall, as our space permits, lay before our readers. The account of the photographic operations in connection with the solar eclipse, and the recent progress of celestial photography as detailed by Mr. Warren De la Rue, will be found in the present number. We have received from Mr. Sutton his paper on "The Panoramic Lens," read in section A, which will appear in our next.

The complete series of photographs taken by Mr. De la Rue in Spain of the progress of the solar eclipse were amongst the most interesting of the multiform scientific illustrations which adorned the Free Trade Hall. They are enlarged from the negatives so as to form transparencies on glass of about six inches in diameter, and show every stage from the first impingement of the moon's disc to the total obscuration, in which the luminous prominences are very beautifully rendered. There were also paper prints showing groups of the whole of the gentlemen of the Spanish expedition on board the "Himalaya," and also a long panoramic photograph of Mr. De la Rue's station in Spain. At the conclusion of the Astronomer Royal's lecture on the eclipse, Mr. De la Rue exhibited some interesting photographic transparencies of the eclipse by means of the magic lantern, including one of the totality, which were very interesting. Of the photographic exhibition held in connection with the association we give particulars in another page.

We may here express our regret that the indisposition of Mr. Mercer deprived the association of one paper which would, we apprehend, have possessed great interest—the application of photography to textile fabrics by dying processes. Mr. Mercer has given much attention to the photographic action of a variety of salts, and we saw a specimen of portraiture dyed on fine muslin. At present we do not see any especial economic value attaching to such an idea; but this in no way detracts from the interest of the researches, as a distinct assessment beforehand of the commercial value of his results would be but a poor stimulus to the enterprise of the experimental philosopher.

The oft-repeated story of Franklin's answer to the enquiry, What is the good of such and such a discovery? is to the purpose here. The philosopher of the lightning answered the question with another: What is the value of a new born babe? It is to the possibilities as well as to the actual results we must look in all experimental philosophy; and we trust Mr. Mercer will be enabled to proceed with his researches, and that we shall not have to wait until another meeting of the British Association before we hear more of them.

Our space precludes the possibility of entering into the subjects discussed at the association generally, much as they interested us, but as we have said, we shall again refer to those subjects having a direct photographic bearing and interest.

THE ART CLAIMS OF PHOTOGRAPHY.

Is photography a fine art? With all submission to our correspondent R. A., and those who hold similar opinions, we maintain that it is. It is both an art and a science, or perhaps more correctly speaking it is, like many of the arts, whether polite or industrial, an applied science, or an art based upon a science. We are not at all concerned to refute our correspondent's arguments, by which he endeavours to prove that photography is essentially a science, although perhaps he would have been more exact if he had simply affirmed that it was a branch of chemical science. Science is the grand foundation upon which all the arts are based, and we readily admit that for the successful practice of the art of photography, a more comprehensive knowledge of science is necessary, than is needed for the prosecution of any other art. We have yet to learn, however, that the necessity for completer education, or higher culture of a given kind in the artist, should involve any derrogation to the art. To succeed perfectly as an art-photographer, the student requires all the art-knowledge of the painter. He should be perfectly familiar with the laws of composition and chiaroscuro, have a perfect appreciation of the balance of forms and of tones, and their value in his work; and be a master of those higher qualities, relating to concentration of interest, expression, &c., which give unity, purpose, and character to a picture. He needs not to learn the mechanical art of drawing, or applying pigments; but in place of this, he must acquire a perfect knowledge of the chemistry of his art, and such a practical knowledge of optical laws as will enable him to choose, and use, his lenses efficiently.

But there is no such difference in the mechanical part of the duties of each as to constitute an essential distinction in the character of the art. If the painter require more skill with the hand, the photographer requires more activity of the brain: if the drawing of the one be more under his own control, the result of the other is generally more absolutely true and exact.

All painting is not fine art; nor all painters artists. Our correspondent "R. A." admitted the existence of photographs which were gems of art, but attributed these to the skill of the artists producing them, not to the art by which they were produced. To "the man, not to the method." Why what trifling is this! Are not all the art treasures of the world of art due to the "man and not to the method?" Are the productions of a Buonarotti works of fine art because he was at once poet, painter, architect, and sculptor, or are these arts fine arts because they are capable of giving form and expression to the grand conceptions of the artist's mind? "Photography *per se* is not," we admit, "a fine art;" neither is painting. Daubins annually covers acres of canvas with paint, and his works sell very well by the square yard; but Daubins is not an artist, nor are his pictures fine art. Painting, like photography, is to a certain extent a mechanical art; like photography, although in a less degree, it requires some knowledge of chemical science, for without an acquaintance with chemical constitution of his pigments, and their action upon each other, the painter would produce sorry results. To the enamel painter the chemistry of his materials is an important study, for on the chemical action of heat upon vitreous pigments depends much of the beauty of his work. But these facts do not detract from the art value of the results, or in any way impair the claim of the methods employed, to a position among the fine arts.

We claim for photography a position amongst the fine arts in so far as its productions are worthy to be called works of art, in so far as it gives pictorial expression and effect to the mind of the true artist; just as in like manner we only admit to painting and the other polite arts the same position on similar grounds. We grant that its range of expression is more limited than that of painting; but in what it can achieve how perfect is the achievement! It cannot imagine. Well, no. Neither can painting. But it can, in a more limited degree, we admit, like painting give effect to the imaginings of the painter; witness the works of such men as Rejlander, Lake Price, and Robinson. It cannot idealize. No: but it can be true, and the rapidity with which it can seize a fleeting characteristic or expression frequently enables it to "snatch a grace beyond the reach of art." It cannot select or combine. Well, as to the combining, that it is a moot point; some photographers think it can; but we will waive that at present. As to selection, however, that is just where the art-photographer's strength lies. He can select, and when he is a true artist, it is in the selection that the value of the picture consists. Position and accessories in portraiture, point of view in landscape, conditions of light, atmosphere, &c., &c., all admit of selection, and in this selection, combined with the manipulation and chemical control, which enables him to give delicacy or force; decision or dreamy atmospheric softness to the whole, consists chiefly the art-character of the result. It can select and has reproduced some of the most lovely forms in which Nature presents herself. And that art which can select, pourtray, and perpetuate beauty we affirm to be a fine art.

A photograph is not a mere mechanical reproduction of whatever is placed in front of the camera, like that given by a mirror, and the truth of which would depend on the mechanical perfection of the mirror. The art character of a good photograph does not even consist in judicious selection only, but on the skilful management of every step in the operations, and the result must depend upon the artist having a distinct conception of what he wishes to produce. With him, and as with the painter, the picture must first exist in his own mind, and he will impress his own characteristic ideas of beauty upon it. Not simply in the varied degrees of mechanical excellence, such as the different degrees of skill and care in a workman may produce in a piece of mechanical handicraft, but the different kinds of pictorial beauty such as the artist conceives, are possible in the photograph. The individual genius of the photographer, as well as that of the painter, may be stamped upon his work. Photography, too, has its masters in different styles, as painting has. The grander phases of imaginative art, it is true, are unsuited to its powers. But in rendering the calm beauties of nature, the graceful and true in portraiture, the unmistakeable purpose and intention in genré pictures, photography can boast of its masters, each having a distinct individuality. Who that has given the subject fair attention has not been reminded of Wilkie and Webster by the genré studies of Rejlander? of Sir Thomas Lawrence by the portraits of Williams? Of Sant, by those of Lacy? Are finer or more characteristic portraits than the Lord Brougham and Lord Derby of Mayall, to be found amongst those of Grant? Are the interiors of Bedford much surpassed by those of David Roberts? In Lake Price we are often reminded of Leslie; in Claudet, of Sir Joshua Reynolds; in Wilson, of Turner; in Heath, of Claude Lorraine; in Mudd, of Constable; in some pictures recently issued by hitherto comparatively unknown artists—Jackson, brothers—we are forcibly reminded of Ruysdael, and other Dutch masters. We know that on reading these comparisons there are some who will charge us with comparing great things with small; but we, nevertheless, maintain that the mental characterstics, the genius, which produced the paintings, are manifested to a large extent in the photographs; that the men are in the best sense of the word artists, and that the works and the process are worthily designated by the term fine art.

We have not attempted in these few remarks to define the term fine art. We have rather chosen to show how photographs comply with the conditions popularly regarded as constituting fine art in paintings, and how, notwithstanding limitation and modifications, the methods by which each are produced, and their excellence secured, are in many of their elements identical in character. That there is much photography which is not art, and few photographers who are artists, we admit; but we repudiate entirely the justice of the decision, which would judge the higher claims of an art by a consideration of its lower phases, and an examination of the works of the bunglers amongst its votaries. But we repeat that we claim for photography the position of a fine art, just so far as it can be used as a vehicle for giving expression to the conceptions or perceptions of beauty, in the mind of a true artist, in the same manner as painting, sculpture, engraving, &c., can embody similar ideas of beauty.

Our correspondent animadverted, in severe terms, on the position assumed by the Photographic Society in relation to the classification of photography in the forthcoming International Exhibition. On this subject we have little at present to say. We give the Council of the Photographic Society credit for the very best motives, and a concern for the honour of the art, in the steps they have taken; but as we have before stated, we cannot but think they have, as the issue shows, made a mistake. We believe that had they appointed a committee, all might have been gained, probably, for photography which could be desired. It is scarcely probable that Her Majesty's Commissioners could have any unworthy desire to insult photographers. In offering a separate room, we believe they offered the best possible thing for every purpose. We regret much the issue, and should the rumour prove true that the Commissioners themselves contemplate appointing a committee, and submitting the names for the approval of the society, we should be glad to see the council avail themselves of the chance of retracing, to some extent, the steps they have taken. We apprehend that the Commissioners will have no difficulty in finding men sufficiently interested in the progress and honour of photography, who are either not connected with the society, or who we apprehend are scarcely committed to the present decision of its council. That photography is rich in men suitable for position, we cannot doubt, when we remember such names as Talbot, and Hunt, and Herschell, and Wheatstone, and Lake Price, and Rosling, and Fowke, and Sir Charles Eastlake, and Sir William Newton, and a host of others. We anxiously wait, however, the progress of events, and confidently hope for photography, from all parts of the world a satisfactory and creditable appearance in the great display of the world's industry, science, and art.

[Several letters on this subject stand over for want of space, but will appear in our next; amongst these will be one from M. Claudet.]

MANCHESTER PHOTOGRAPHIC EXHIBITION.

The exhibition of photographs in the Exchange, at Manchester, is by no means the least interesting of the various displays of science and art opened to the members of the British Association, and is of sufficient excellence to render it matter for regret that it is only intended to be of a temporary character.

The first feature that strikes us on entering the room, and glancing around, is the fact that notwithstanding the short tenure of the Exhibition, there is more attention to classification and arrangement than we have often seen in collections of photographs intended for exhibition during an entire season. We find, for instance, prints from collodio-albumen negatives, all hung together, and so with those from oxymel, Fothergill, and other dry collodion processes. Then we see prints from wax-paper, wet collodion, and calotype, all separately classified, so that we do not find it necessary to examine the corner of every picture—there is no catalogue—for details of the method of its production. Then we find landscapes together in one place, portraits in another, reproductions in a third, illustrations of photolithographic and photoglyphic processes in a fourth; illustrations of photochemistry, and the results of different printing processes without the salts of silver in a fifth, and so on throughout. The pleasure and instruction derived from an examination of specimens so classified, and the facility in remembering them which it affords, are materially enhanced by this arrangement. The time and thought bestowed by the committee in the first instance, are reaped a hundred-fold by visitors afterwards.

Perhaps one of the most interesting contributions to the exhibition, is half-a-dozen frames of old calotype portraits, many of them twenty years old. Some of our readers may remember them, for those who have seen them will not readily forget them; we refer to those of Hill and Adamson. We say it with some hesitation, because after twenty years progress it seems a somewhat unpleasant admission to make, but these portraits excel in interest, at least, ninety-nine per cent. of the photographic portraits produced at the present day. There is a grandeur, a power, an absence of the common-place and vulgar, which forcibly reminds one of the best paintings by some of the old masters. True their tones are brown and rusty, there is an absence of delicacy and minute detail; but the arrangement and massing of lights and shadows, and above all the easy, natural, but thoroughly artistic management of position and accessories constitute the chief charm. We strongly commend a study of these pictures, for position and arrangement, to all portraitists who have the opportunity of examining them. There is nothing strained, nothing theatrical, nothing unusual, but there is nothing vapid and common-place. The educational influence of a study of these pictures, in that respect, we consider to be invaluable. As regards the permanency of these old calotypes, so far as we can judge, they are little changed: their shadows are brown, and their lights perhaps in some instances slightly yellow; but they do not exhibit the symptoms of decay so often seen in pictures of a much later date, when "his sulphur majesty" began to reign over the destinies of photographic prints. The gentlemen who produced these pictures will produce no more in conjunction. Dr. Adamson is dead: Mr. Hill, whose name we now see associated with Mr. McGlashen, has contributed two or three pictures to the present Exhibition, which, with the modern improvements of the art, combine many of the qualities which give such value to the old calotypes.

We now turn our attention to the collodio-albumen pictures. As might be expected, in Manchester, the Exhibition is very strong in this process, the specimens occupying the whole of one side of a long room. We are bound to add, moreover, that the quality is equal to the quantity, and that a non-photographic observer, if directed to choose a process by the results here exhibited, would inevitably select the collodio-albumen. Amongst the exhibitors in this department, foremost both as regards numbers and excellence, are the specimens of Mr. Mudd. We have so often described and praised the pictures of this gentleman, that our readers are perfectly familiar with their characteristics. Considered as a whole, in selection of subject, position, and light, and in manipulation throughout, they are the best photographs we know. This opinion may largely arise from our admiration of many of his subjects, but to us there is an indescribable charm in his treatment of them, there is such delicacy, detail, and texture combined with great vigour, and the unmistakeable presence of atmosphere, all combining to make a perfect photographic landscape. We do not, in saying this, in the slightest disparage the skill of many other excellent photographers, whose productions we admire; we simply mean that these please our individual taste most. Mr. Mudd has here several new pictures, some of which have fine natural clouds, a somewhat unusual accompaniment to prints from collodio-albumen negatives. Of these the "Valley of the Tay" is a fine specimen; and another, "Scawfell in Clouds" has a very striking effect, the top of the "pike" or peak, being hidden in the clouds which drive over its summit. Another good picture of moorland scenery is "Eskdale from Birker Fell," a panoramic picture, printed from two negatives on one piece of paper, making a picture about 21×9 inches. One of the best amongst Mr. Mudd's new pictures is a "Bridge over the Braan near Dunkeld." The rustic stone bridge, embowered in, and surrounded by beautifully rendered foliage, the transparent water and its fine reflections, all contribute to make a picture leaving little to be desired. Another picture which pleased us with its thoroughly transparent water reflecting some glorious foliage, is entitled "Wood and Water." Mr. Mudd has several other fresh pictures, of which, however, the limitations of our space preclude a description at present.

Mr. Sidebotham contributes some of the finest collodio-albumen pictures in the Exhibition. Amongst the best of these is one of Chepstow Castle; if this picture had been a little less cold in tone it would have been perfect. The composition is very fine, the view including a portion of the shingly beach, and some shipping, as well as the castle. Mr.

Sidebotham in this and two other very fine pictures, a view of "Tintern Abbey," and one of "Fountain's Abbey," avoids a fault very common amongst many young, and some old, photographers, that of making the building fill the picture, so as to exclude entirely its surroundings. Now it often happens that a large share of the beauty and character depend on these, not only as suggestive of the *genius loci*, but as materially adding to the value of the composition. In all these pictures there is exquisite delicacy without the slightest loss of force. Mr. Sidebotham has also a very large picture about 20 inches by 14 inches, of "Strine's Cottage," this is less valuable as a composition, but is very fine photography.

Mr. R. O. Clark exhibits some very artistic collodio-albumen pictures, chiefly views in Edinburgh. They are all, more or less, good pictures and fine compositions, notwithstanding some movement occasionally in the figures. A view of "Cowgate" is very perfect indeed, as is also one of the "High Street." Many of these pictures are full of atmosphere, and leave but one thing to be desired; that is, the absence of some manufactured clouds. We do not say that every attempt to introduce by artificial means clouds into a photograph is rank heresy; but it is a matter in which the legitimacy must be decided by the result. The unsuccessful rising of a people against constituted authorities is rebellion, and the rebels are condemned to die; the successful issue of the same rising would be revolution, and the revolutionists establish a new dynasty. When clouds are introduced into a photograph so that they pass for those of nature, or even to the practised eye only raise a doubt of their origin, they may add much to the effect of the picture; but when they strike at a glance as manufactured articles, it is a pity they should deface good pictures. The simpler the forms, and the fewer the number of introduced clouds the better will be the result; but a multitude of small clouds, with some attempt at drawing in their forms, are rarely successful. These remarks must not be taken, however, as bearing reference to all the pictures of Mr. Clark: they are suggested by one or two, but the majority of his pictures are very fine indeed, and exhibit much artistic feeling.

Mr. Edward Mann exhibits a few very good photographs amongst which we may mention a most charming picture entitled "High Torr, in Derbyshire," and also a schooner, being apparently an instantaneous picture on a dry plate. Mr. C. Buxton exhibits some very fine Egyptian and other eastern views, taken on collodio-albumen plates, which, if not equal to Frith's, will bear in many respects not unfavourable comparison with them. Some very fine collodio-albumen pictures are exhibited by Mr. Wardley, and some also by Mr. A. Smith, a pupil, we believe, of Mudd's.

There is a collection of upwards of a dozen 10 by 8 specimens illustrating the modification of Petschler and Mann, taken we believe by Mr. Petschler. These are chiefly scenes in Derbyshire; they are well selected and well manipulated, and constitute in many respects very fine pictures; but we are bound to add, with all deference to the opinions of many excellent photographers, that we do not think the process as here exhibited bears favourable comparison with the collodio-albumen proper. The pictures lack brilliancy and crispness; there is a slight dullness and heaviness which strikes us as belonging to the process, and is the only fault of many otherwise excellent pictures.

The hot water process and the tannin process each put in an appearance, but not in great force. By the latter a fine and large picture, about 16 by 12, is contributed by Mr. J. Annan, "Loch Ranza, Arran." It has some suspicious looking clouds, but as it is marked "untouched" we are bound to believe it is so. Mr. Annan also contributes some excellent pictures by the wet process. The only prints from "hot water" negatives are by Mr. J. H. Young, and are very good. There are some transparencies by the same process, but the tone strikes us as unpleasant for transparent pictures.

The waxed-paper process has not many exhibitors, but those we see almost make us regret that this process is little more than a thing of the past. Mr. Sidebotham, Mr. Wardley, and Mr. Hooper, each exhibit some fine specimens: one or two of Mr. Sidebotham's, we think, scarcely to be surpassed by any process.

A frame of instantaneous stereoscopic pictures is exhibited by Messrs. Smyth and Blanchard, chiefly consisting of views in London, and on the Thames. Amongst some of rather mediocre merit, there are a few that are exceedingly fine. "Sunset on the Thames at Greenhythe" is a charming picture of water, cloud, and atmosphere, scarcely surpassed by anything we have seen of this kind.

There are two or three very charming little pictures by Wilson, of Aberdeen. They are described as "Taken with Dallmeyer's triple achromatic lens, No. 1, focus 7 inches." The pictures are about 7 inches by 4½ inches, including an angle of about 60°, and giving perfect definition all over. As was remarked by several connoisseurs looking on, one of the great charms of these pictures is the wide angle giving such a large amount of subject. This is a point to which we are glad to see much attention has been given of late amongst the photographers.

The consideration of the wide angle naturally brings us to Mr. Sutton's panoramic lens and pictures. A complete set of apparatus sent by Mr. Ross, and one of the specimens before noticed in our pages, "The old church at St. Brelades, Jersey," excited much attention, and the specimen was much admired.

Mr. Brothers contributes some very fine specimens of portraiture and reproduction. A copy of the large group of officers of the 84th, the picture measuring 48 inches by 21 inches, excites a good deal of admiration. It is unquestionably one of the most successful specimens of composition grouping we have seen. Mr. Brothers also exhibits some cartes de visite and coloured portraits. A coloured photograph on ivory is peculiarly beautiful, soft, delicate, and transparent.

There are two or three solar camera pictures, but all coloured. Whether contributed by the photographer or colourist, is not stated; but they are not such as will enhance the fame of either. One a portrait of the celebrated tenor, Giuglini, is a positive libel. Giuglini is really a gentlemanly-looking, and somewhat handsome man, with a clear, but deep Italian brunette complexion; this is a coarse face, with hue of brick dust; and as if to enhance the unpleasant effect, light blue is the tint prevailing in the background. The other, a portrait of Mr. S. Smyth, is a more carefully finished picture, but the flesh is very raw. It looks as if Apollo's flaying process, recently described by Oliver Wendell Holmes, had just been accomplished, and done somewhat cruelly, the god cutting somewhat deeper than is his wont.

Mr. H. P. Robinson contributes a few very good pictures; "Early Spring" is a charming landscape. An illustration from Tennyson's "Idyll's of the King," "Elaine with the shield of Launcelot," is, in many respects, a very fine picture. The conception and composition are good, the model is charming, and the photography satisfactory. We are reminded, however, of a criticism of Ruskin's on an Academy picture of a child rescued from drowning by a dog. After praising the drawing, &c., Ruskin says, naively enough, "I never saw a child pulled out of the water by a dog; but *wouldn't its clothes be wet?*" Now the shield which awakens Elaine's fantasies would, we think, show more dints and bulges, traces of the heavy usage which make her exclaim—

> "And ah, God's mercy, what a stroke was there,
> And here a thrust that might have killed !——"

Mr. Robinson is a good artist, and has produced some very fine pictures. This is one of them; but it might have been improved by a little more thought here, we think. In the same direction errs another very noble picture of the same class Mr. Robinson contributes, entitled "The Lady of Shallott." This picture is full of poetry; is finely conceived and executed. It has, however, a few minor faults of detail. As we shall have more to say on this picture than our space here permits, we defer comment for a separate notice.

We have only space to briefly indicate many other excellent and interesting specimens, some of which are old favourites and have been noticed in these pages before. There is one of Mr. Kibble's instantaneous pictures of a steamer at full speed, sea and fine clouds, produced, we believe, on a collodio-albumen plate. Mr. Heath has some excellent specimens of landscape, as also has Mr. Dixon Piper. Mr. Herring some fine specimens of portraiture and reproduction; and also a very interesting frame of psychological studies, consisting of portraits of the same persons during insanity and after restoration. Mr. Mayall has some of his recently issued large portraits of statesmen and cartes de visite of the royal family. Mr. McAndrew has some very fine portraits. Cundall and Downes a series of reproductions of Turner's "Liber Studiorum."

There are very interesting specimens of various printing processes with uranic and other salts, some old Daguerreotypes, and other specimens connected with the early history of the art, and some microscopic specimens contributed by Mr. Dancer. Specimens of various photo-engraving processes by Herr Pretsch; specimens of zincography by Col. James. Some few other specimens may possibly have escaped our attention, as the temporary character and purpose of the Exhibition did not render the preparation of a catalogue desirable. The Exhibition is throughout, notwithstanding, one of the most interesting we have visited.

PURE PHOTOGRAPHIC PAPER.

There are so many difficulties in the manufacture of photographic paper from rags, arising from accidental mechanical impurities, that not even the most scrupulous care on the part of the manufacturer suffices to avoid them. The imperfections arise chiefly from particles of metal, bronze, or iron, from the knives employed in cutting the rags; occasionally there are others arising from the consistence of the paper pulp, which accumulates in little knots.

What the photographer requires is a homogeneous cellulose paper, and it seems likely that the beautiful and important problem of producing it is solved by the transformation of wood into a pulp suitable for making a strong paper, eminently adapted to printing of all kinds; but especially for engravings, and which may be advantageously substituted for the China or India paper now in demand for proof impressions.

This problem had previously been solved in a scientific point of view, but the process was too expensive for industrial application. It was necessary to act upon the wood in the state of shavings, with large quantities of soda, in the form of a hot and concentrated *ley*. The recent improvement of the process is suggested *by a lady* of an active and intelligent mind, who has quite overcome the obstacles which seemed to stand in the way of an economical production of the wood paper, and consequently presents to the manufacturer a white paper pulp at a price of about one half the cost of rags. Her secret consists almost entirely in a new dividing implement, which reduces the wood to a condition resembling lint or tow, at a single blow, which is afterwards readily acted upon by the cold alkalies and acids required to bring it to the state of pure cellulose, which is subsequently bleached by chlorine.

The dividing instrument, or cutting machine, is a kind of steel hedgehog; it consists of a series of parallel vertical wheels, armed with fine points, which are made to pass under pressure into the substance of the wood in the direction longitudinal to its fibres. The points penetrating to a very minute depth into the wood, say the thickness of a sheet of paper, produce on the upper layer of wood a kind of canvas of woody threads; a plane then placed transversely across the wood removes this layer of threads, which constitutes the lint or tow-like substance which is ready to be acted upon by the soda and chlorine. Under these conditions, a power of three or four horses suffices to furnish in the course of four-and-twenty hours the materials for a ton of pulp, without the aid of the cutting cylinders required for reducing rags to a pulp, and consequently with a great economy of the motive power.

A great many varieties of paper may be produced by an admixture of the pulp of rags with that of the wood, 10 to 20 per cent. of the former to 90 or 80 per cent. of the latter. The texture, thickness, and colour of the wood paper may be varied also at pleasure by modifying the fineness of the cutting machine and other resources. Specimens have been submitted to repeated and careful trials at the hands of lithographers, copper-plate, and letter-press printers, who report unanimously in favour of the new paper, which costs only one-tenth the price of India-paper. It now only remains to test its suitability for photographers, of which, *à priori*, there appears but little doubt. This discovery seems quite providential at a time when the scarcity of paper-yielding material causes great anxiety in the minds of those who see the demand constantly outstripping the means of supply.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Nitric Acid.—This important acid is usually prepared on the large scale by distilling commercial nitrate of soda—Chili saltpetre—with oil of vitriol in large cast-iron cylinders. Owing, however, to the difficulty of getting this salt pure it is preferable for the experimentalist to prepare it on the small scale from nitrate of potash. This salt is not easy to obtain free from chlorine, and as this latter body is a very annoying although a very frequent impurity in nitric acid, it is advisable to take some pains at the commencement to get rid of it. The purest commercial saltpetre (nitrate of potash) should be obtained in the first instance: this should be tested for chlorine by dissolving a crystal or two in water, and adding to the liquid a drop of nitrate of silver solution. If a white precipitate takes place, showing the presence of chlorine, the whole of the nitre to be employed should be purified by crystallization. For this purpose dissolve as much of the salt as possible in hot distilled water, filter, if necessary, from suspended impurities into a clean evaporating dish, and set on one side to cool; taking care to keep out the dust by a cover of bibulous paper. When cool the bottom will be most likely found to be covered with crystals of nitrate of potash; pour the supernatant liquid from them into another dish and allow the crystals to drain. When dry test one of them with nitrate of silver as at first recommended. It will, in all probability, be found to be free from chlorine. If, however, it should still be impure a second recrystallization will render it fit to use. The mother-liquor poured off the pure crystals of nitre will most likely yield a further crop of pure crystals, or if not quite pure they may be rendered so by a second crystallization. In this way the impurity of chlorine may be gradually eliminated, until by a judicious series of crystallizations the whole will be found concentrated in a small volume of liquid which may be thrown away without any loss worth mentioning.

The nitre having thus been obtained free from chlorine, powder it finely, dry it, and place 100 parts in a glass retort with 96 parts of oil of vitriol. The ingredients should only be sufficient to about half fill the retort otherwise there will be danger of the mixture boiling over. The neck of the retort must be connected to a proper condensing tube, and the extremity of this must pass far into the receiver; no cement being used for any of the connections. The nitre must be put into the retort first and then the oil of vitriol. If the retort be tubulated the acid may be poured in through the opening, but if not it must be introduced down the neck by means of a bent funnel tube, and care must be taken not to soil the neck of the retort, with any of the acid. Heat must now be applied by means of a deep sand-bath, and the mixture submitted to distillation until the residue in the receiver is tranquil and no more drops come over. If the nitre has not been quite purified from chlorine, there will be at the commencement of the process an evolution of a yellowish red mixture of hyponitric acid vapour and chlorine gas. As the whole of the chlorine will come over at the commencement of the distillation, the distillate should be tested from time to time by allowing a drop or two to fall into a dilute solution of nitrate of silver. As soon as a white cloud ceases to be formed, when the acid and silver mix together, the receiver should be changed, and a perfectly clean one placed in its stead to receive the remainder of the distillate which will be perfectly pure nitric acid. The neck of the retort and the condensing tube should be cooled by a current of water trickling over it, and the receiver should have wet bibulous paper surrounding it, which is kept constantly wet with a stream of cold water. If the operation has been properly conducted from 100 parts of pure nitre, there will be obtained about 66 parts of nitric acid 1·5 sp. gr. This may be further concentrated by mixing it with half its volume of oil of vitriol and distilling it again at a low temperature, until only sulphuric acid is left in the retort. The distillate will, however, be contaminated with sulphuric acid, from which it must be purified by distilling it again, from a few crystals of nitrate of potash. Thus purified and concentrated nitric acid is a colourless transparent liquid (frequently, however, coloured yellow by hyponitric acid). It has a faint but characteristic odour and a highly acid taste, reddening litmus, and exercising a highly caustic and corrosive action on organic substances, staining those containing nitrogen, such as the skin and nails of a yellow colour. When very strong it absorbs moisture from the atmosphere becoming gradually weaker. In its concentrated form, it has a specific gravity of 1·52 and contains one atom of the anhydrous acid with one atom of water. In this state it decomposes in boiling, evolving stronger acid, and becoming ultimately of the specific gravity 1·42, when it boils regularly at 248° F. Nitric acid dissolves copper with evolution of yellowish red nitric oxide gas, producing a green solution. When slightly diluted with water, it attacks tinfoil, producing an insoluble white powder. It has no action on gold, platinum, and some of the rarer platinum metals, unless it is mixed with hydrochloric acid. With these exceptions it attacks and dissolves all metals forming in most cases crystallizable nitrates. Its use in the manufacture of nitrate of silver has already been described in our former chapters, and is too well known to our readers to need further mention at present. Nitric acid is also the agent used in the manufacture of gun cotton. Our readers are likewise so well acquainted with this operation that further comment upon it is needless. Carbon is oxidized by strong nitric acid, a piece of red hot charcoal plunged into concentrated acid continuing to burn with vividness. Sulphur is oxidized by it into sulphuric acid; the action, however, is difficult to carry on until all the sulphur is oxidized, unless the latter is finely divided, and the acid very strong: if the liquid be boiled the sulphur fuses, and the action is slow. Nitric acid mixed with hydrochloric acid forms a mixture of chlorine, water, and hyponitric acid, which is usually called *aqua regia*, from its property of dissolving gold, the "king of metals." When a nitrate is dissolved in a little water and mixed with twice its volume of oil of vitriol, then allowed to cool, and a crystal of protosulphate of iron dropped in, it assumes at the surface of contact a rose, purple, violet, or blackish brown colour, according to the quantity of nitrate present; the smallest trace of the latter being sufficient to produce a red tinge. This is one of the most delicate tests for nitric acid, and is frequently of great use, as it is occasionally of importance to ascertain whether nitrate or nitric acid is present in any given solution.

What is commonly known as fuming nitric acid, or nitrous acid, is properly speaking a mixture of nitric acid containing but a small quantity of water, with hyponitric acid. It is obtained by distilling 2 parts of dry powdered nitre with 1 part of oil of vitriol. At first, half of the nitric acid present passes over in the form of ordinary strong nitric acid; the temperature then has to be considerably raised, when the other half of the nitric acid comes over being split up into oxygen and hyponitric acid. The oxygen goes off whilst the hyponitric acid is absorbed into the nitric acid already in the receiver. It is thus seen to be a mixture of two separate acids, and is quite a different substance, chemically speaking, from real nitrous acid. It forms a yellowish red liquid, of a specific gravity of 1·536, and emits fumes of the yellowish red colour of hyponitric acid, but darker.

When diluted with a small quantity of water, the colour changes to olive green, an evolution of nitric oxide gas taking place; a larger quantity of water changes it to pale blue, and a still further addition renders it colourless. This fuming acid has even stronger oxidizing properties than nitric acid itself of an equal degree of concentration, and is therefore to be preferred to the pure acid, where it is required merely for its powers of communicating oxygen to other bodies.

THE NITRATE BATH AND ITS TROUBLES.

SIR,—I have had some difficulty lately with my nitrate bath, and as it caused me some trouble in getting right again I have thought that a narration of my experience might be interesting. Usually I am very successful with my bath, and it is the one thing among my chemicals that I never trouble myself about. I have even presumed myself upon it, and when I have heard and read about others having to do this and that to their baths, I have thought how much better I fared who never did anything to it. But many persons, beginners especially, really have a mania for punishing their bath. They seem to think that a plain unsophisticated solution is too uninteresting to perform their exploits with, so they proceed to doctor it, administering homœopathic or allopathic doses of acids and alkalies alternately. The originally vigorous constitution is entirely undermined by this physicking, it can't stand it, so it becomes ailing and weakly, requiring frequent attention, occasionally change of air, now and then a little sunshine, often refreshment, and sometimes a good rest. The last fashionable recipe, when it is squeamish and out of order, is to put it through a course of oxide and nitric acid. A rival school of professionals pin their faith to acetate of soda and acetic acid. There are those again who believe only in ammonia and carbonate of soda, and when doctors differ who's to decide? With Shakesperian air then I exclaim, "Throw physic to the dogs, I'll have none of it," and content me with a solution of plain unadulterated nitrate of silver. For many years I have worked with a primitive solution of this character, and well has it served me, only requiring refreshing occasionally with crystals and water. But recently my good old friend has given indications that all was not well with it. It could not do the work it formerly did; it was inclined to break down with half the number of whole plates that it formerly carried with ease; it had evidently passed its grand climacteric, decay of nature had set in; it had fallen into its sere and yellow leaf. It might, however, be only overwork; possibly there was life in the old bath yet; perhaps the hot weather and hard work had been too much for it, the "cartés de visité" might have been too many for it, and like its master it required its autumnal relaxtion. A little rest, some change of air and a good bronzing in the sunshine, might re-invigorate it and him too.

To remedy existing evils then an entirely new bath was determined to be made. This reminds me an of anecdote. I was one day buying some photographic articles in a shop when a gentleman entered, evidently an amateur, and addressing the proprietor said, "Oh, if you please there is something the matter with my bath, can you tell me what it is?" "What *is* the matter?" said he. "Oh, it don't work well." "Perhaps it is you that don't work well." "I am sure it is the bath, it is quite out of order. Can you tell me what to do with it?" "Yes, I can. "Do tell me, please, for I am so anxious to take nice pictures." "I can tell you how to prevent that bath giving you any more trouble." "Pray what *shall* I do with it," said the man hurriedly. "*Pour it down the sink and make a new one.* I adopt that plan myself. and never knew it once to fail," was the cool reply. The gentleman looked "sold," bought two ounces of crystallised nitrate, and retired crestfallen.

In my present distress I bethought myself of the advice of this *disinterested* shopman, which struck me, however, as being more summary than logical. I did not see the necessary connection between the two clauses. If I poured the old bath down the sink, of course I must make a new one; but then I might make a new one without giving my old friend the sack. And this resolve I took, for I felt sure my old servant was not entirely done up, it was only temporary indisposition, overwork, and want of rest, digestion out of order, been taking some nasty iodide that did not agree with it, perhaps the alcohol had got up in its head; or the ether might have prostrated it; at any rate I labelled it "old and disabled," and putting it on the superannuated shelf, thought that, like an old pensioner, it might do me some service yet in the day of need. My invalid bath tenderly disposed of, I proceeded to make a new one, using similar nitrate of silver to that I have been in the habit of using for long time, 4s. per ounce, 3s. 9d. for five ounces—I generally save the odd threepence's, they pay for my News. I made my bath in the proper manner; dissolved the silver in a small quantity of distilled water, put in a little iodide of potassium to iodize it, added the rest of the water, agitated well, and then filtered. I then added the small quantity of acid I usually find necessary to make it work clear, and proceeded to take a picture. Judge my surprise when I poured on my developer—I always work with iron—to find the whole plate fogged. What new trouble is this? thought I; again and again I tried with similar result. I added a little more acid, still fog; put more and more acid, until a very serious quantity was introduced, and though an improvement was effected, still nothing like a decent picture could be propuced. I therefore gave it up for a bad job, put it into a separate bottle, and labelled it "insane,"—it was clearly deranged, and beyond control—and I placed it beside my old and disabled bath. I proceeded then to make another new bath, being determined this time to avoid all chances of error, and watch everything closely as I went along. I was careful before, but this time I would be doubly so. I commenced by washing out my glass measure with strong nitric acid, served my glass bath and dipper the same; selected only the best formed crystals of nitrate, weighed them carefully in the clean glass pan, dissolved them properly in distilled water, got a new glass stirring rod, used some iodizing solution this time to iodize with, and finally filled up with the rest of the water and filtered. I now tested, and it was neither alkaline nor acid, simply neutral, and I added just that small quantity of pure nitric acid, that I knew by long experience ought to make it work right. Whatever mistake there might have been in my former bath, I was certain there was none in this, so with considerable anxiety I tried a plate, using my regular collodion and developer. How shall I describe my mortification at seeing the same fogging as before. I felt I could dance with rage and passion; I should like to have thrown bath and chemicals out of the window, and I am afraid the language I used was more energetic than polite.

At this period a customer came in and diverted my thoughts, must have a portrait at once, could not wait; so I took down my old effete bath that I had *not* thrown down the sink, and did the best I could with it, and bad was the best. This together with some dinner enabled me to cope with the bath again. I knew that adding acid in any reasonable quantity was no use, and I suddenly thought of Laborde's method of adding iodine to prevent fogging. Certainly your own remarks and experiments were not very assuring, but when a man is in trouble he will do anything to extricate himself, so to make a long story short, I tried the iodine dodge in several ways, small doses first, large afterwards, but excepting producing yellow precipitation and causing frequent filtrations, I saw no change whatever, and certainly no relief from the fog. I consider the iodine plan a failure, it did not answer with me or cure my bath. I then thought of another plan, adding ammonia to alkaline and exposing to the sun. Fortunately a blazing sun was out that day and my bath got a good cooking. the bottle nearly roasted, the solution nearly boiled. It quickly turned muddy and nearly black, ah! thinks I, there's the fog separating at last, presently I'll filter it out. The ammonia has acted as a purgative, and expelled the foul matter; the poor solution has certainly had something that did not agree with it, that it could not digest; nothing like a good clearing out when the stomach is out of order." So I filtered it, and had the satisfaction of seeing a black sediment on the filter-paper. I acidified it with nitric acid till litmus paper was decidedly red. Now I thought I was all right; and to give my bath the very best chance, I cleaned a few plates unusually well, and carefully collodionizing one, immersed it in the bath. Oh how anxiously I waited the two or three minutes it was being sensitized. I exposed it on my printer's devil—the boy who breaks all the negatives and swears they were cracked before—and hurriedly rushed to develop. "To *fog*, or not to *fog*, that is the question" with me; how I watch the young imp as he "comes out;" his snub nose and dirty shirt were never so interesting before. Yes, the picture is out; now for the cyanide, when lo, as the iodide disappears it reveals my old enemy spread all over the plate. There is the young image nipped in the bud, choked with the fog, not only killed but buried under it too. Who shall describe my vexation and mortification at such a finish to all my labours? I flung myself into my uneasy chair, and felt inclined to give up the fog and the ghost at the same time.

What *shall* I do? For two days I had been putting off my customers, and they would be put off no longer, and my head was as full of fog as my bath. This time I really did feel inclined to follow the tradesman's advice and pour the bath down the sink, there to associate with other muddy solutions. I bottled it however, and, considering the several ineffectual attempts I had made to get it in order, I felt warranted in labelling this one "incurable," and I put it beside the others on the shelf—my photographic hospital I called it. Matters were now serious with me, and I sat down to reflect on the probable causes that produced this trouble. It was no use making a third bath as I had made the former two. The nitrate bath is formed of distilled water and nitrate of silver, and one of these must be the cause. I now remembered reading of persons complaining that they could get no good silver. Mr. Hardwich used to deliver long lectures on impure nitrate of silver; at the time I smiled at all this because I was never bothered from this cause, but now these facts were brought fully home and I sympathised where I formerly laughed. I thought that my turn had now come to have a spell of bad silver. It *must* be the silver—it could be nothing else *but* the silver—why had I not thought of that before? So out I went, bought some fresh silver, went to one of those shops where they are supposed to sell something superlatively perfect—and where they make you pay for it too, whether it is or not—and gave five shillings an ounce for it. It did not *look* any better than what I had at home. The proof of the pudding is in the eating thought I, so I made a new bath, exposed a fresh plate, and, will you believe it? To my shame I must confess it, *it* was as foggy as any of my preceding ones. How humbled and mortified I felt those only know who have passed through similar trials. To think that I who could advise everybody, *I* who never got into trouble, I who laughed at others when they spoke of a foggy bath, should make bath after bath and find them all useless.

But it was no use indulging in self-depreciation. That would not set me right. One more patient was added to my hospital, "complaint unknown." The nitrate of silver was not the offender, for that obtained from the immaculate chemist at the heavy price was no better than that obtained from the less pretentious tradesman. There was just one chance more; the distilled water, clear and transparent as it looked, *might* be the real delinquent. I had heard of persons in out of the way districts making their baths with common river water, and in sheer despair I set about to make one more new bath with the silver I ordinarily use, my faith being shaken in the more expensive article.

As I expected, the solution was very milky with the chloride and carbonate of silver formed, but filtration set all that to rights, and after adding the small dose of acid required, I prepared another plate. Of course I expected to see my old enemy, in fact I had almost despaired of ever getting a clean plate any more, when to my astonishment the picture developed clear and brilliant without a vestige of fog. Hurrah! three cheers!! "Richard's himself again." "Here John," I called out to my assistant, "run after that gentleman and bring him back; tell him it was all a mistake, he *can* sit to-day." Thus I traced out my enemy at last. It was not the traduced nitrate, it was the deceitful water; the silver remains untarnished, and the water is condemned.

Henceforward photographers take warning by my fate; and when your newly-mixed, and slightly-acid baths fog, do not hastily condemn your silver, but look sharp after your water, and on a case of emergency, do not be afraid of using good clean household water, even to make a bath with.

An Old Hand.

British Association for the Advancement of Science.

THE PROGRESS OF CELESTIAL PHOTOGRAPHY.

BY WARREN DE LA RUE.*

At the Aberdeen meeting I had the honour of communicating to this section a report on the state of celestial photography in England, which has since appeared in the Transactions of the Association. Since that period, I have pursued my investigations in this branch of astronomy, and ascertained some facts which I believe will be of interest to the meeting. In the first place, I beg to recall to the recollection of members who may have read my paper, and restate for the information of those who may have not done so, that it was intended at the period of the Aberdeen meeting, that the Kew photoheliograph should be taken to Spain, in order, if possible, to photograph the luminous prominences, or, as they are usually called, the red flames, seen on the occasion of a total solar eclipse. The words implying a doubt as to the success of the undertaking were advisedly inserted, because so little information could be collected from the accounts of those observers who had witnessed previous total eclipses as to the probable intensity of the light of the corona and red flames in comparison with other luminous bodies. My impression was that I should fail in depicting the prominences in the time available for doing so, because I had had the Kew instrument tried upon the moon, and failed utterly in getting even a trace of her image on the sensitive plate, and the corona and prominences together were supposed not to give as much light as the moon. I therefore pointed out the desirability of other astronomers making attempts to depict the phenomena of totality by projecting the image of the prominences direct on to the collodion plate without enlarging it by a secondary magnifier, as in the Kew instrument. It was fair to assume, with the great experience I had acquired in celestial photography, that I should succeed with the Kew instrument if success were attainable, and I knew that far more reliable results would be obtained by this instrument than by the other means I recommended should be employed as the surer means of obtaining some record. Two theories existed, as is well known, to account for the red prominences,—the one prominently supported by the Astronomer Royal was that they belonged to the sun; the other, which is still supported even by an astronomer who obtained photographs of them at the last eclipse, was that they are produced by the diffraction of the sun's light by the periphery of the moon. It will be seen, therefore, how essential was it not only to obtain photographic images of the prominences, but also how important it was to obtain such perfect images of them that they could not be confounded with the purely diffraction phenomena, if such existed, and that the images should be on such a scale that the defects common to collodion could not be confounded with them. "The pretty near" would have been far more readily accomplished; but having the whole bearing of the subject fully impressed on my mind, I preferred to make a bold venture, and either accomplish what I aimed at or fail entirely. Fortunately I was successful, and to that success the steadiness of my staff much contributed. We now know that the luminous prominences which surround the sun, for they do belong to him, can be depicted in from twenty to sixty seconds, on the scale of the sun's diameter equal $\frac{4}{3}$ of the object glass employed. That is to say, an object glass of three inches aperture will give a picture of the prominences surrounding a moon four inches in diameter. The next subject I have to call your attention to is the photographic depiction of groups of stars, for example, such as form a constellation like Orion—in other words, the mapping down the stars by means of photography. I have made several experiments in this direction, and have obtained satisfactory results; and I believe that, at last, I have hit upon an expedient which will render this method of mapping stars easy of accomplishment. The instrument best adapted for this object is a camera of short focal length in relation to the aperture like the ordinary portrait lens, the size of lens being selected to suit the scale of the intended photographic map; and the camera of course mounted on equatorial stand, with clockwork motion. The fixed stars depict themselves with great rapidity on a collodion plate, and I have experienced no difficulty in obtaining pictures of the pleiades by a moderate exposure even in the focus of my telescope, and they would be fixed much more rapidly by a portrait camera. The difficulty in star-mapping does not consist in the difficulty of fixing the images of stars, but in finding the images when they are imprinted, for they are no bigger than the specks common to the best collodion. It is of no service attempting to overcome the difficulty by enlarging the whole picture; but something may be done by causing the images of the stars, which are mere spots, to spread out into a cone of rays by putting the image out of focus, and thus to imprint a disc on the plate instead of a point. Last year has been so fully employed that I have not yet had time to fully develop this method, but I have ascertained its practicability. Some curiosity naturally exists as to the possibility of applying photography to the depiction of those wonderful bodies, the comets, which arrive generally without anything being known of their previous history, and absolutely nothing as to their physical nature. It would be valuable to have photographic records of them, especially of their nucleus and coma, which undergo changes from day to day, and hence such a means of recording their changes as photography offers would be the best beyond comparison, if the light of the comet were sufficiently intense to imprint itself. On the appearance of Donati's comet in 1858, I made some attempts to delineate it with my reflector on a collodion film, but without success; and on the appearance of the comet of the present year, I made numerous attempts, not only with my telescope, but also with a portrait camera, to depict it, but even with an exposure of fifteen minutes (minutes, not

* Read on Thursday, September 5th, in Section A.

seconds), I failed in getting the slightest impression, even with the portrait camera. Hence this conclusion may be arrived at, that the actinic ray does not exist in sufficient intensity in such a comet as the last to imprint itself, and, therefore, photography is inapplicable to the recording of the appearances of these wonderful bodies. I now return to heliography. Experiments conducted at the Kew Observatory by my request, have shown that for an image of the sun of any given size when once the aperture of the telescope has been ascertained which is sufficient to produce the picture with the necessary degree of rapidity, it is not beneficial to increase that aperture, that is to say, no more details are depicted, nor does the picture become sharper so as to bear a greater subsequent enlargement in copying than when the smaller aperture is used. It has also been ascertained experimentally that it is not well to enlarge the image beyond a certain point, by increasing the magnifying power of the secondary magnifier, so as to cause the rays to emerge at a greater angle. These results are such as I should have anticipated; but as it was nevertheless desirable to produce pictures of the sun's spots, with a view to their closer study, on a scale considerably greater than the pictures produced by the Kew Observatory instrument, I commenced some operations of my own for trying whether it would be possible to procure such pictures with my reflector. On maturing my plans, I found that the apparatus which it would be necessary to append would be so weighty, that the telescope would require to be strengthened considerably, to support the additional weight in the awkward position it had to be placed, and it did not at first appear how this could be conveniently done. Ultimately, I found the means of adding a radius bar, and of supporting the plate holder which carries a plate 13 inches square, at a distance of four feet from the eye piece. But here another difficulty occurred, namely, that the image of the sun was so powerfully heating, that if allowed to remain for a very short time on the instantaneous slide, it heated it and ultimately set fire to some part of the apparatus. A trap easy to be moved over the mouth of the telescope had to be contrived so as to open just before the instantaneous apparatus was brought into action, and again shut immediately afterwards. At last these mechanical difficulties were surmounted, and I commenced my experiments to ascertain the best form of secondary magnifier; these experiments are still in progress, and some important difficulties remain to be overcome before pictures of the sun's spots will be obtained with that degree of sharpness which shall leave nothing to desire. With an ordinary Hayghonian eyepiece, employed as a secondary magnifier, and placed somewhat nearer the great mirror than its position for the most perfect optical picture, in order to throw the chemical rays further on, so as to bring them to focus on the plate, I have obtained some sun pictures of very considerable promise on the extremely large scale of the sun's diameter equal 3ft. These pictures have only been very recently procured, and I submit them to the section because I believe that an interest is felt in the progress of celestial photography, and that our members prefer to take part in the experiments as it were by watching their progress, rather than to wait until the most perfect results have been brought about. I may state the mechanical and chemical difficulties have been surmounted, and the only outstanding one is the form of the secondary magnifier. When this has been worked out, perfect sun pictures three feet in diameter will be obtainable with a telescope of one foot aperture in less than the 20th of a second of time. These pictures, when taken under suitable circumstances, may be grouped so as to produce stereoscopic pictures, which must throw considerable light on the nature of the spots. It appears to me that such results must be of value to science, and that such records of the state of the sun's photosphere, both as regards spots and other changing phenomena, which are obtainable by means of photography, are worth collecting and discussing. It is agreeable to me to work out the problem, so as to point out the means by which success is attainable, and I may for a time carry on the records; but it will, on reflection, be seen that these observations, if continued as they should be for years, are likely to prove a serious tax upon the leisure and purse of a private individual.

Professor Chevallier said that having been in Spain during the eclipse, he could bear testimony to Mr. De la Rue's achievements. He himself had the opportunity of making one experiment, which showed that the light of the corona was brighter than that of the moon; for the light of the corona was visible through a thickness of glass, which on trying it on the moon extinguished the light. The whole scientific world was indebted to Mr. De la Rue for paying such great attention to a branch of science promising such important results, more especially as applied to the delineation of the stars.

The Rev. Dr. Robinson thought that the matter ought not to be left with mere praise and admiration of what Mr. De la Rue had done. The means by which the Association had done so much in fulfilling its mission of a benefactor of mankind, was by acting uniformly on the principle that whenever a member was found gifted with peculiar aptitudes and powers, his services should be secured, and himself encouraged to press forward with his work. It was clear that the way was open to a new department of knowledge—that a new instrument of research was at command. Let them avail themselves of it to the fullest extent. They certainly had no right to trespass upon Mr. De la Rue's zeal or time; but he (Dr. Robinson) was sure that if they followed up the question, they might reckon upon Mr. De la Rue's assistance in directing and superintending. He hoped that an application would be made by the section to the Committee of Recommendations; and he had no doubt that the Royal Society would join in affording the means, to a great extent, of prosecuting the researches so successfully begun.*

The President said that it was impossible to over-value the importance of the self-registration in all ways. A good many years ago, at his instance, the Association took up the subject of the self-registration of magnetic phenomena, which had been further carried out by the assistance of money from Government. It was certain that the more recondite observations became, the more it was felt that man was a very poor creature, and that matter was very superior to him. Only put a machine in order to do work, and it would do it much better than any man could. Mr. De la Rue had spoken of the precision with which he got images of the stars. The precision was so great that the images were so small that they could scarcely be made out—not from want of visibility, but because they were scarcely distiuguishable from spots on the collodion. Some time ago, in America, the difficulty was the other way; for, from the state of the atmosphere, the images of the stars were in a constant shake, so that every instant there was a different image, and the result was impressions rather large and blurred. He trusted that the time would come when the transit of stars would be made to register themselves The means were not wanting; because in America the course of a star across the field of a telescope had traced itself photographically. It would not be difficult to arrange so that this course should refer itself to seconds of time on a transit clock. The image was continuous so long as the light showed itself; but by galvanic connections with the beat of the clock, it was possible at every second to stop the light, so that a succession of images would be got, giving a distinct register of time by the star, and thus, to some fraction of a second, it can be fixed when the star passed a given point of view. He wished specially to call attention to one of the photographs—an image with the edge of the sun; and he wished all to observe the rapid degradation of light towards the edge. It was maintained by M. Arago that the light of the sun did not decrease sensibly to the edge; that it was uniform throughout. That was never his (the President's) opinion; and he gave to M. Arago some reasons for differing from him. If M. Arago did not choose to believe him, he had reasons for his doubt; but if he disbelieved the evidence of this photograph he would have no reason for so doing. It was a matter of public scientific importance that the use of the photograph for the things now referred to should be perfectionated; and as he fully concurred in what the Rev.

* We here remark that £150 was subsequently voted by the committee to be placed under the control of Mr. De la Rue.

Dr. Robinson had said, he thought it was most desirable that the Committee should confer with Mr. De la Rue, with a view of securing that effective and direct superintendence without which, in such observations, nothing like practical advance could be made.

ON DEVELOPMENT BY IRON, WITH SUBSEQUENT INTENSIFYING BY IODINE WITH RE-DEVELOPMENT.

The advantages gained by iron development for negatives is in many instances of the utmost importance. Where objects liable to move are being photographed, it is one of the greatest helps that has been gained by the photographer. Negatives developed by iron, however, seldom have sufficient density to yield vigorous prints: it is, consequently, necessary in most instances to have recourse to some intensifying process, by which vigour sufficient for good printing may be gained. Various plans of giving density to feeble negatives have from time to time been proposed; but I am inclined to think that for simplicity and certainty of good results, no plan has been advanced equal to that by iodine with subsequent re-development.

The plan I have been in the habit of following, and which has yielded most satisfactory results, is as follows:— The collodion used is prepared in accordance with the formula for negative collodion given in the Photographic News Almanac for 1861. Nitrate bath, 35 grs. nitrate of silver to 1 oz. water (neutral). Expose about half as long again as for a positive. Develop with a ten grain solution of iron, to which half a drachm of glacial acetic acid has been added just before use. Development is carried out till all detail is brought out, being careful not so push it so far as to veil the extreme shadows. Fix in a weak solution of cyanide; wash well.

If the exposure has been well timed, the picture will now have all the appearance of a good negative by reflected light; but on being viewed by transmitted light, although all detail is visible, it will be much too transparent to print. The density may, however, be brought up to any degree by the following intensifying process:—

The formula for the iodine intensifying solution given in the Photographic News Almanac of 1861, is too strong; it is difficult to cover the plate with it, so as to obtain equal action over the whole surface. A solution of half the strength (iodine, 1 grain; iodide of potassium, 1 grain; water, 2 ounces) will be sufficient, and a large plate may be covered equally before the action commences. Considerable care is required in the application of the solution of iodine, so as not to carry the action too far; in which case the chances are that the negative gets spoiled.

I have lost several excellent pictures by over-doing them with iodine. If the deposit of silver in the film gets converted into iodide through its entire thickness, it is almost impossible to bring up the density by any amount of re-development. It is best to convert a very thin layer only of the deposited silver into iodide. The plan I have found to succeed best is as follows:—

After having well-washed the fixed picture, and before it has had time to dry, carefully flood the plate with the iodine solution, allow it to remain on till the thinnest parts of the deposited silver just begins to show a tendency to take a whiter shade; then throw off the solution, and wash very well. When the iodine is well washed from the film, pour over it repeatedly the ordinary pyrogallic developing solution; then expose to a strong light for a few minutes: a slight darkening of the lights of the picture takes place during the exposure. Now carry the plate to the dark room, and re-develop with the pyrogallic solution, to which a few drops of silver solution—nitrate of silver, 20 grains; distilled water, 1 ounce—has been added. The intensity of the picture comes rapidly up, and may be brought to any degree, by renewing the pyrogallic solution with silver; a moderate degree of intensity in the negative, however, will be found to give the most brilliant prints; by making the lights too intense, you get only a hard inharmonious print.

The negative when finished will show from the *glass* side as a good positive.

This method of intensifying may be carried out either before or after the picture has been dried after fixing; but, if done after drying, the film has a strong tendency to tear from the edges of the glass, which is a chief fault in other intensifying processes. If the intensifying is done before the plate has been dry, the film will bear any amount of washing under a tap without showing the slightest tendency to give way.

The plates, if kept in a close tin box, will remain quite wet for at least 24 hours; but if it is wished to keep them longer, I have no doubt that a solution of glycerine in water poured over them would keep them moist any length of time. I have, however, never tried the glycerine, not having had occasion to keep my plates more than ten or twelve hours. T. C.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 11th September, 1861.

I am inclined to think that the greatest "revolution in photography" will be effected by M. Bertsch's contrivances for the successful working of *automatic* photography, which possesses great claims upon the attention of amateurs, inasmuch as it enables the operator to obtain *certain* results with the least possible expenditure of labour and skill. Moreover, it reduces the baggage to a minimum, which, of a certainty, is not the least important element in the "revolution."

Photographers are under great obligations to M. Bertsch for the many ingenious contrivances he has provided for their use, but none compare in value and importance with his automatic camera, with its accessories, which need occupy only a corner in a dressing-case or writing-desk. Arrived at the scene of action, the photographer is relieved from the care and trouble of focussing, an operation, which with ordinary cameras, is so tedious and uncertain, except in experienced hands. With the automatic camera, images are obtained so accurately, that even when magnified three hundred times no deformity is apparent. A description of the apparatus, and of the theory upon which it is constructed cannot, I think, fail to be interesting and useful to photographers. The construction of the automatic camera is based upon the law of the principal focus, and not upon that of the conjugate foci, and, consequently, it admits of our obtaining from a point ten paces distant from the instrument to the extreme horizon, all the planes of the landscape with due distinctness, whatever be their relative distances. The negatives obtained with this little instrument are so delicate, that they may be submitted to an enlarging of three hundred times, if upon collodion, or of six hundred times if upon albumen.

The camera when placed at the same distance from the objects in the foreground at which the artist places himself in studying from nature, gives to every object composing the landscape the same relative dimensions they appear to have to the eye Far from presenting, as the photographs taken full size at once on the spot do, the aspect of a flatness as if on a canvas, the proofs obtained by the automatic camera possess a real perspective exactly conformable to that presented to the eye by the natural objects themselves; this result is due to the sharpness and prominence of the foreground.

A simple illustration will demonstrate the advantage these proofs possess over those obtained by ordinary methods: if the operator wishes to apply the law of optics which permit him to obtain a landscape wholly in focus, from the nearest objects to those most distant, he will proceed as follows:—

Suppose that he wishes to take a proof of the dimensions of 20 square inches, to have it all in focus the objective must have a focus of 65 inches. With such an instrument it will be necessary to place the camera 140 yards from the foreground. At this distance the nearest objects subtend at angles so small, their dimensions, relatively to the horizon, will be so insignificant, that they will become confounded with the more distant planes, and contribute only very feebly to the perspective effect. Artists are quite justified in condemning this radical defect in photography. For what painter would place himself at a distance of 140 yards from his foreground in studying from nature?

In making a rational application of the laws of optics, M. Bertsch has rendered this service to photography:—of permitting the travelling photographer to obtain proofs under the same conditions in which the artist places himself in copying nature. Taken at a dozen paces from the objects constituting the foreground, the negatives of the automatic camera are stereographs of remarkable fineness, and, upon being enlarged, yield the most natural perspective effects; they are true pictures, deficient in nothing but colour.

M. Bertsch has reduced the entire baggage of the travelling photographer working with wet collodion in the open air, to the following dimensions: the laboratory, which contains the camera, chemicals, dishes, and all the indispensable appliances, is but 10 inches long, 4 inches wide, and 14 inches deep. It resembles a landscape-painter's colour-box, which, upon being opened, is converted into a little dark-room or tent, which admitting one hand only, by means of a little sleeve, all the preliminary operations of wet collodion, sensitizing, introducing the plate into the camera, developing and fixing after exposure, are performed. The camera is a copper cube four inches square, which is screwed on to a walking stick, which opens to form a tripod. Previously regulated for all distances, this camera requires no focussing; it has no ground glass, and in order to ascertain if the desired landscape is refracted upon the sensitive plate, it is only necessary to observe if it occupies and fills the little frame placed on the top of the camera. The laboratory will contain chemicals sufficient for more than one hundred proofs.

For enlarging the negatives of the automatic camera, M. Bertsch has constructed a simple instrument which is readily put in operation. In stating that this instrument is only an application, to the picturesque, of the microscope with which the inventor has reproduced almost invisible objects of natural history in colossal dimensions, it is scarcely necessary to remark upon the fine detail it gives to the proofs.

In applying these principles to the automatic camera, M. Bertsch has constructed a complete little apparatus, which is a camera that scarcely covers the palm of the hand, and with which, without focussing, we can obtain, for any distance, those little portraits of the size of a pins' head, perfectly sharp and distinct, which have become all the rage. It is very curious and interesting to look at these microscopic points through a powerful magnifier, and see them transformed into pictures full of the minutest detail.

SUNDAY PHOTOGRAPHY.

Sir,—As the question of sunday-trading in photographs has been lately causing more than the usual amount of attention to this subject, a few words on the matter will not be amiss.

It has been suggested that this practice should be put down, but how? that is the question, and a most difficult one to solve. In this country we do not like interference with private trade, no matter what kind of commerce it may be, so long as it is not a nuisance or a danger to the general public. Now it may be a very difficult thing to prove, sir, that if I or you, or any one else choose to work within our own rooms, and receive pay for our work on Sundays, that we are doing anything that can be brought under the cognizance of the police; how then can we bring these parties within the cognizance of the law?

A correspondent in your last suggests that it would be best for photographers to demand that they should be taxed to the extent of £10 or £20 a-year, but I submit that this would be a thing not to be thought of in these free-trading times. The tendency has been for some years past to disenthral trades and professions from taxation of all kinds. Even the lawyers' fees have been reduced, that he pays for permission to fleece Her Majesty's subjects, and shall the most liberal and most advancing of all professions set the example of retrogression, by placing a heavy tax on the practice of its various branches, and thus burden those who without having offended are made the scapegoats for others' sins? If government proposed such a tax on the practice of our beautiful art, there would be a never-ending cry against such a burden.

But if the law cannot interfere, and we may not tax these people, how then are we to proceed? Could not the clergy and the most respectable class of the population take this matter in hand? for I submit that it is the general public and not the photographic world who have the real power in the matter. It is an axiom of free trade that supply and demand keep pace with each other, hence I infer that the demand must be made to cease ere the supply can be cut off; indeed the supply will fail as a natural consequence; for this reason I repeat that the cause and the remedy for sunday-trading in photographs is in the hands of the public.

Every respectable photographer would, as a matter of course, be delighted to see an end to these vile dens where photography is daily made the means of victimising numbers, who not being, unfortunately for us, learned in art, are imposed upon too often at a price at which a conscientious man would be glad to supply them with a genuine art photograph, nor would a tax, I opine, be a sufficient guarantee against the system complained of. It has become almost a proverb, that real talent, and the possession of means, are seldom combined in the same individuals, at least not at the commencement, and how many really clever and respectable men might be deterred from entering the profession, because they had not money to pay for a licence? and who could tell how much loss it might be in the future advancement of the art, to keep men of ability out by such tyrannical means? and would it deter those who bring so much disgrace on the profession from fear of the expense? Why, sir, I am told that many of these Sunday traders take £4 and £5 on a Sunday, and even more at times; and as most of this amount is I presume taken in low priced portraits, it will show at once where the blame really lies; it is the public who support these dens who are the parties really in fault, and *time* with the increase of *art* education, the supply of *good* work at a *moderate* price by respectable men, and the admonition of those who can best influence their flocks appears to me the only sure remedy for what has become to all classes; both those who create and those who supply the demand, a very great evil.

The only excuse I can make for the length of this communication is the importance of the subject and the necessity for a right understanding of the means at our command for rectifying the evil.—I am sir, yours respectfully,

E. E. L.

[The public unquestionably have the matter largely in their hands; but we are afraid that the portion of the public who support Sunday photography are not very accessible or amenable to argument on the subject. As we have before said the law cannot interfere with the private Sunday practice of photography or any other profession, but when it becomes an overt act, and, as in the case of touting, a public nuisance, the law can and ought to interfere.—Ed.]

Photographic Notes and Queries.

Stereo Exchange Club.

Dear Sir,—I am also of opinion with other members of the above club that some better regulations are desirable. I do not, however, think the suggestions I have seen would prove perfectly satisfactory. Under the present arrangement each individual member is completely ignorant as to the negatives possessed by the others, consequently he has not the least idea of what he will receive in return for those sent out. It is very probable that some members possess views which would be highly valued by others, but who are not aware of their existence. I think you will agree with me that this information is very desirable.

The plan I, therefore, propose is that every member should forward to you (or to some other disinterested and competent gentleman who would kindly consent to act as adjudicator) a print from *all* his negatives, so far, at least, as regards those he wishes to exchange. These to be formed into a list to be sent to each member, who would thereby be enabled to make a selection from the different subjects by intimating he should wish to receive certain views in return for his own. If you considered any of the prints forwarded were not up to the mark, *these to be excluded from the list*, and their omission would convey the necessary hint as to their quality far better than by hurting one's feelings by any classification. The lists to be re-issued as often as may be thought advisable, perhaps every two months during the summer would not be too often to give members the opportunity of having the new stereo's they had taken added to the list, first having them submitted for approval as before.

By this means each member would feel *certain* of getting no inferior prints, and would also have the advantage of selecting the subjects he wished.

The cost of printing the lists would be but trifling, and I do not think the members would object to the slight expense and the trouble of sending you the prints, when the advantages derived would be so considerable.

A somewhat similar plan to this was suggested by Mr. Henderson last year (p. 311, vol. iv), but as it only partially obviates the defects at present existing, I think the above alterations to the scheme are necessary for its thorough efficiency. —I am, dear sir, yours truly, Stereo Ex.

To Correspondents.

*** In compliance with the wishes of many of our subscribers we have thought it prudent to defer the completion of the fifth volume of the Photographic News until the end of the year. The termination of the volume at the end of eight months is complained of as indefinite and troublesome; a volume containing the whole of the numbers issued during twelve months it is thought will be more convenient for reference.

*** It has just come to our knowledge that at least three or four letters addressed to us by post have never reached our hands; a circumstance to which we shall have to call the attention of the Post Office authorities. Since the same thing may have happened in cases of which we at present know nothing, we shall esteem it a favour if any of our correspondents who may not have met with attention, will communicate with us again, and let us know as definitely as they can the date and place of publication of such letters.

Susanna.—We cannot just now refer to the formula to which you allude; but you will find the following answer your purpose for developing negatives to be intensified: protosulphate of iron 15 grains, glacial acetic acid 15 minims, water 1 ounce, with sufficient alcohol to make it flow freely. Our correspondents, in making reference to matters which have appeared in the News, and desiring information regarding them, should always give the page and volume. They would then save us many hours of unnecessary labour in seeking for the subjects to which they refer.

W. O. W. S.—Mats and preservers are chiefly made in Birmingham, we cannot give you the names of makers; but may mention Mander as one of the best. Trays, cases, &c., are made both in Birmingham and London, by a great many makers. You will probably see their names in our advertising columns from time to time.

A Troublesome Photographer desires us to inform him "which is the best and cheapest photographic journal that is published up to the present time," adding, "I don't care whether it comes out weekly, monthly, quarterly, or otherwise; I want you to advise me the best to take," &c. Take! Why take the Photographic News, to be sure; we, of course, think it best, and of course strive to make it such. Take all the others if you can afford it; but by all means take the News; being the only weekly photographic paper, it must furnish the fullest and most prompt information.

A Junior Photographer.—The tide runs in this direction. Another enquirer wishes to know the best monthly or quarterly journal devoted entirely to photography. There is no such quarterly journal, and the only monthly journal is that of the Photographic Society, which is chiefly devoted to a record of its own proceedings. The only Photographic Dictionary published, except that in our pages, is Sutton's, which is now out of print. We believe a new edition is contemplated; but cannot tell when it will appear. We think it is not commenced yet.

F. L.—Avoid the use of nitric acid for an iron developer for negatives. Use acetic acid in equal proportions to the iron.

Josephine.—The best method of recovering silver from your waste baths, washing water before fixing, &c., is to keep a large stone jar holding two or three gallons; into this turn all solutions containing nitrate of silver, and put in from time to time a handful of common salt. This will throw down the silver in the form of chloride, and after standing a few hours you may pour off the clear solution, which will contain no silver. When a large quantity of chloride has accumulated, take it out, dry it, and begin again. The reduction of the chloride into metallic silver is scarcely a suitable operation for a lady. It will be best to sell it to the refiners, who will give you either cash or nitrate of silver for it. The same with regard to waste prints and clippings of sensitive paper. Bear in mind that it is only before they are fixed that these are of value. You will see the address of persons who purchase these things, occasionally, in our advertising columns. You may remove prints from the toning bath into clean water, and leave them there until all are toned, so as to fix the whole at one time, and not be attending to two operations at one time.

G. S. E.—The addition of a very small quantity of acid to your bath, or of a little tincture of iodine to your collodion, will probably remove the streaks. Look carefully to the surface of your bath before commencing to operate. Sometimes such streaks are caused by scum on the surface. Gum may be used for mounting, but it should be very thick and freshly made, as it soon turns acid. If made with boiling water it will keep about a week. Scotch glue or starch are better for the purpose.

J. G. L.—More details regarding toning processes will appear in our next. In the mean time you may use with advantage 1 grain of chloride of gold and half a drachm of acetate of soda in three or four ounces of water. 2. The collodion you name is not particularly well suited to iron development. 3. As the Stereoscopic Exchange Club at present stands, it is necessary to send specimens for our inspection. If the new arrangement come into force, the duty of inspection will be undertaken by the secretary.

J. H. Crampton.—The dissolving of the film is a casualty which occurs at times with all spirit varnishes, especially where highly rectified alcohol has been used in their manufacture. It depends, however, chiefly on the condition of the collodion. Some pyroxyline is partially dissolved by absolute alcohol: it is generally of the powdery kind. There are only two ways that we know of to avoid such an occurrence; the first is to be very careful, when the tendency is present, to apply the lowest possible degree of heat which will prevent chilling; and if that fail, to use another sample of collodion.

Excelsior.—The use of skimmed milk or serum of milk as a preservative for dry plates is very similar to the Fothergill process, and the manipulations are the same. You will find the best resume of the manipulations in the various dry processes of the Photographic News Almanac for this year. A Lerebour's landscape lens for views, 14 by 12, we should consider cheap at £2 10s. The quality of the lenses we consider good.

A. B. C.—It is difficult to say whether your negative be in fault or not from the print forwarded; but it is probably a little too thin. The chief fault of the print is that it is considerably over-toned.—Use the formula given above to J. G. L. Use a stronger silver bath, print in the shade, and tone less and more slowly. For glass positives use a nitrate bath of 35 grains with one drop of nitric acid to each ounce of solution. Develop with protonitrate of iron; or protosulphate 15 grains, glacial acetic acid 15 minims, nitric acid 1 minim.

Susanna.—To prevent the film leaving the plate, use, if you can, a nitrate bath with less acid. Let the film set well before immersion, and if these fail try another and less contractile sample of collodion. The spots to which you refer on the edges of Dr. Hill Norris's plates are at times caused by contact with deteriorating influences while keeping, and are most frequently met with in under-exposed plates. Expose more fully. If that fail, send a piece of a negative to Dr. Hill Norris, and he will have pleasure in helping you.

J. P. C.—The best resumé of the manipulations in the various dry processes is in the Photographic News Almanac for this year. The best details of the collodio-albumen process you will find in Mr. Mudd's article in our issue of August 16th. We have given several articles in the production of transparencies during the present volume; see pages 208, 221, 257, 280, and others. We are glad to learn that the treatment of the bath we recommended was successful.

The Secretary.—If you procure achromatic lenses, in pairs, of 5 or 6 inches focus, you doubtless may be able to mount them in wood so as to answer the purposes of the exhibition. We cannot tell you where to procure them cheap. Those by French makers are generally lowest in price. As it is a thing we have never done, we cannot give you certain information. The best stereo transparencies we know are those of Mr. Breeze of Birmingham, and next, those of Soulier and Ferrier. Their recent instantaneous views of Paris would be interesting in your exhibition. Mr. Fry has done some very fine ones, but we do not know whether he is publishing any at present.

J. L.—The chief faults of the pictures enclosed appear to be over-exposure in a very dull light, and over-development. Good views of landscapes cannot be obtained in a bad light. We are not fond of acetate of silver in the bath for dry plates. The addition of acetic acid to your bath would make the plates a little less sensitive, but would aid you in obtaining brilliancy.

G. S. S.—We are glad to see that there is considerable progress in your results, and that you have a correct appreciation of what is required. By all means remove the "stopping out" from the sky. Turpentine will probably dissolve the black varnish, and a little gentle friction will remove it without hurting the spirit varnish underneath. The letter shall appear.

Eothen.—You will find further information respecting Bertsch's automatic camera in the letter of our Paris correspondent in the present number. We are not aware of the price, or of any agent in this country.

Enquirer, H. A. B., James Maginn, and several other correspondents, in our next.

Letters from several correspondents and other articles in type are unavoidably compelled to stand over till next week. Our absence from home attending the meetings of the British Association, has caused unavoidable delay in attending to some communications.

THE PHOTOGRAPHIC NEWS.

VOL. V. No. 159.—*September* 20, 1861.

PHOTOGRAPHY A FINE ART.

We call the attention of our readers to the full and lucid treatment this subject has received at the hands of our correspondents who answer "R. A." The masterly and exhaustive statement of the case by M. Claudet, we think, must carry conviction to the minds of the most prejudiced. In our next we shall have one or two further remarks on the subject, and on the recently published letter of M. Silvy, in which he, in point of fact, admits the whole question in dispute. The length to which the correspondence on this interesting question has extended compels us to defer much other interesting matter.

IRON NEGATIVES AND BRILLIANT PRINTS.

In resuming this subject we will, before speaking of the development, make a few remarks on diffused light in the dark room and camera as one of the most common sources of veiled shadows.

We may remark at the outset that where bromo-iodized collodion and iron development is used, much more stringent conditions, as regards the presence and the colour of the light, are necessary than where simply iodized collodion and pyrogallic development are used. The recent examinations of the coloured glass used in dark-room windows which we have undertaken for our readers, has made apparent the fact, that a very large proportion of the glass used for that purpose is a very insufficient protection to the sensitive plate in the dark room, when working the process of which we are speaking. In many of the samples of glass forwarded, whilst the blue, violet, and lavender rays are effectually excluded, the green, as well as the yellow and red, are admitted. Now, as bromide of silver is sensitive to the green ray, it follows that just in proportion to the amount of that light admitted, and the amount of bromine present in the collodion, will be the amount of general reduction, chiefly manifesting itself by a deposit upon the shadows and general veiling of the picture. We believe this is a common but unsuspected source of lack of brilliancy in iron negatives. The general appearance of the negative does not suggest such a source of error, because in pyrogallic acid negatives a thoroughly buried picture was not uncommon, and its printing qualities not seriously impaired by the condition. But, as we explained in a previous article, such a condition is fatal to brilliancy in an iron negative.

Another, and equally unsuspected source of veiled shadows in negatives by this process is diffused light in the camera. With simply iodized collodion, except when quite new, and pyrogallic acid development, the tendency is to reduction only where a brilliant light has acted; feeble rays are ignored, and hence it is that pictures with violent contrasts are produced without drawing in the shadows. With bromo-iodized collodion, and iron development, the opposite tendency is manifested; wherever a feeble ray of light has acted on the film of bromo-iodide of silver, the iron developer causes reduction. And thus it is that unobserved diffused light in the camera is acting all over the plate feebly, at the same time that the more brilliant light from the objects in focus is producing an image. This diffused light may proceed from several sources. The fact should not be forgotten, which is, however, scarcely ever remembered, that the lens is, in reality, a window in the camera; and whilst concentrated light from objects in focus passes through it, diffused light from every source which can reach it, also passes through. To some of our readers this fact may never have occurred, and, considerably startled, they may exclaim, "But how is this to be prevented?" It cannot be prevented entirely, but it may be reduced to a minimum, and care may be taken that when light has passed through the camera window, it shall meet with no reflecting surfaces, and be prevented, as much as possible, from falling on the sensitive plate. In a glass room there is always, of course, between the sitter and the camera, a certain amount of window, both at the top and side of the room, from which light is proceeding to the lens. As much of this as possible, it is desirable to cut off. As the rays of light from the objects in focus proceed to the camera in the form of a cone, the apex of which is just in front of the lens, a box or tube, blackened inside, should be attached to, or placed in front of the lens, widening towards the sitter so as to avoid cutting off any of the cone of rays which form the image in the camera. If such a box or screen as we have described be made to project about a foot in front of the lens, so as to cut off as much extraneous light as possible, the result, to those who have not before tried it, will be as gratifying as unexpected, in its effect on the cleanness of the shadows, and the brilliancy of the negative.

One of the next important considerations is to get rid of surfaces having the slightest power to reflect light, even when it has passed through the lens. To this end, the mounting of the lens should be carefully examined, and every part of the interior of the tube which could, by possibility, reflect light, carefully blackened with an absolutely dead black. The interior of the camera next demands attention. In a small camera a simple lining of black cotton velvet will be found more efficient than any method of colouring it black. If the camera be large, something more than a mere lining is desirable. A series of three or four diaphragms with apertures of graduated sizes to suit the shape of the cone of rays as they proceed from the lens to the sensitive plate, will be found invaluable. They may be made of wood or cardboard, covered with black velvet. All strong light entering the camera will thus be most effectually prevented from reaching the sensitive plate.

These precautions may at first appear trivial and unnecessary. To operators accustomed to simply iodized collodion and pyrogallic acid development in its less sensitive conditions, it is very probable they will do so. But we again affirm, that with a bromo-iodized collodion and iron development, conditions of a much more stringent character in this respect are necessary, and that on the attention to such minutiæ, much of the brilliancy and perfect printing qualities of iron negatives depend.

The development of the negative will next be the subject of some remarks.

Scientific Gossip.

Photography has been so frequently applied to microscopic purposes, especially in relation to micrometric appliances, that it will be interesting to our readers to know to what degree of minuteness their reductions can be carried without exceeding the limits of microscopic resolvability. The question as to how small a space can exist between lines, and still admit of their being separated under the microscope has long been undecided. The late Professor Queckett placed the limit of resolvability at the 1-75,000th of an inch; Mr. Ross placed it at the 1-80,000th of an inch, and Mr. De la Rue, in his extended examination of Noberts' test plate was unable to resolve any lines closer than the 1-81,000th of an inch. From this it would appear that the actual limit was about the 1-81,000th of an inch, which does not much vary from the theoretical deductions of Fraunhofer, and others based upon the physical properties of light. On the other hand there are authorities who assert that lines much closer than the 1-85,000th are resolvable: thus Messrs. Harrison and Sollitt have given measurements of striæ as close together as the 1-130,000th of an inch, and Mr. Sollitt in repeating these measurements expresses an opinion that lines as close together as the 1-175,000th of an inch can with proper means be seen.

Such being the conflicting testimony of distinguished microscopists, and the capability of the modern object glass for separating lines, it will be of interest to have additional evidence on the matter. This has recently been afforded by Messrs. Warnley and Sullivant, who have published an analysis from actual measurement of one of those marvels of art, Nobert's test plates. They were assisted in their research by instruments of unexceptionable quality, employing 1-12th and 1-16th object glasses, and one 1-30th, of 160° angular aperture by Tolles. In addition to this an amplifier, consisting of an achromatic concavo-convex lens, was introduced between the object glass and the eye-piece, by means of which a power of 6,000 diameters was obtained. Sunlight passing through appropriate achromatic condensers was employed to illuminate the test plate. The test-plate used consisted of 30 bands of lines, each band varying but little from the 1-2,000th of an inch in width, and having its lines a uniform distance apart. On one end was engraved the distance apart of the lines composing the various bands. These distances being in the 1st band 1-11,248th of an inch; in the 10th band the 1-40,943th of an inch; in the 20th the 1-67,413th of an inch; and in the 30th the 1-90,074th of an inch; in the other bands the lines being of intermediate distances apart. A careful analysis of this plate, with every microscopic appliance for distinct and accurate vision at the higher powers, showed that up to the 26th band there was no serious difficulty in resolving and ascertaining the position of the lines; but on this and the subsequent ones, spectral lines—that is, lines each composed of two or more real lines, more or less prevailed, showing that the resolving power of the object glass was approaching its limit. By a suitable arrangement, however, of the illumination, these spurious lines were separated into the ultimate ones on the whole of the 26th, and very nearly the whole of the 27th band; but on the 28th, and still more on the 29th, they so prevailed that at no one focal adjustment could more than a portion of the width of the band be resolved into true lines. The true lines of the 30th band they were unable to see. These experiments, which were repeated a considerable number of times, induce the authors to believe that the limit of resolvability with the best modern object glasses is about the 1-87,000th of an inch; but that this limit may possibly be carried somewhat higher, as the great advances recently made in the 1-30th object glasses shows that these have not reached a stationary point of perfection.

It would be an instructive study to ascertain the number of patents which have been and are daily being taken out for effecting the same object. Whether the subsequent patentees are really ignorant that the novelty for which they seek protection is already in common use, or whether the complication of the patent laws is such as to enable some trivial modification to be incorporated into and patented with an already known design we know not, but certain it is that most of the photographic patents which are now published seem to possess no novelty whatever. For instance, a patent has recently been taken out for a *novel* arrangement of the dark chamber used in photographic operations, which serves as a laboratory for effecting the sensitive process, and for taking and developing proofs in the open air with wet collodion, whereby these operations are performed with ease and rapidity. "On two sides of the dark chamber are placed two gutta percha troughs; one of the troughs contains a bath of nitrate of silver, and the other a bath of sulphate of iron. The troughs are hollowed at those parts where the glass plate is placed, and they are provided with external flanges, which allow of an inclination of 45° and even more, for certain positions without the liquid therein contained being spilt, which renders the apparatus suitable for transport. By this disposition of the apparatus the glass plate treated with collodion may be successively dipped into the two baths without its being taken out of the dark chamber, the motions of the said plate being suitably controlled by mechanism actuated from the exterior of the box." What in the name of all that's photographic does the patentee mean to claim? The description as far as we can make out from the above is simply a very old contrivance already patented by Mr. Newton, and used or suggested in endless modifications by correspondents in our columns; but whether the patent is for using gutta-percha troughs, or for putting them inside the camera, or for using baths of nitrate of silver, and sulphate of iron, or for using a camera at all, is more than we can attempt to say.

We have to report upon a few more specimens of glass which have been received since publishing our last account.

No. 21. F. R. This is a deep olive-green glass. In the spectroscope the spectrum is seen to be diminished to the red, yellow, and green rays, part of the extreme red being cut off, and all the blue, indigo, and violet being obliterated, except concentrated light is employed, when some of the blue rays are seen to come through. This glass would be no protection with collodion containing bromine, and very little with an iodized collodion One peculiarity of this glass (which it possesses in common with many others), is that red flowers examined through it can scarcely be distinguished from the green leaves with which they are surrounded.

No. 22. W. C.—An orange glass coloured with silver. This cuts off the violet, indigo, and blue rays in a very perfect manner, and would be quite applicable for photographic purposes. This glass is curious, inasmuch as it possesses in a remarkable degree the false dispersion mentioned by Professor Stokes. It reflects from one side when placed on a piece of black velvet a peculiar bluish green light; or when placed on a sheet of white paper the scattered light partakes of that mixture of blue and brown which is ordinarily distinguished as a puce. (Hunt.) Of this variety of glass Professor Stokes makes the following remarks:—Orange coloured glasses are frequently met with, which reflect from one side, or rather scatter in all directions a copious light of a bluish green colour, quite different from the transmitted tint. In such cases the body of the glass is colourless, and the colouring matter is contained in a very thin layer on the surface of the plate. Referring to this, Mr. Hunt, who has examined this glass, states that this is not always the case; in the glass with which the present experiments were made the colouring matter, silver is diffused throughout the mass. The peculiarity in question is produced on one surface by exposing it to the influence of the flame of burning smoke. Professor Stokes continues: as this phenomenon was supposed by Sir John Herschel to offer some analogy with the reflected tints of fluor spar, and a solution of sulphate of quinine, I was the more desirous of determining the nature of the dispersion. It proved on examination to be nothing more but false dispersion, so that the appearance might be conceived to be produced by an excessively fine bluish-green powder contained in a clear orange stratum, or in the colourless part of the glass immediately contiguous to the coloured stratum. The phenomenon has, therefore, no relation to the tints of fluor spar, or sulphate of quinine.

23. H.—A piece of yellow oiled silk has been sent by this correspondent. It would be of use to examine many various kinds of flexible media, such as horn, thin gutta

percha, india rubber, and oiled silk, either in their natural states, or artificially coloured, as if a suitable obstructing medium could be found amongst these substances, it would be a great advantage over the use of glass, inasmuch as its non-liability to break would render it an invaluable accompaniment to the photographic tourist, who might have his tent almost all window, instead of admitting the illuminating light as at present through the most jealously guarded aperture. The piece of oiled silk under consideration is, however, scarcely up to the mark, although it is better than yellow calico, or tammy. Examined in the spectroscope, considerable quantities of green light, acting on bromide of silver, come through, and a trace also of blue light when sunlight is used to illuminate the slit.

ACTION OF LIGHT ON THE COMPOUND OF FERROCYANIDE OF IRON WITH OXALATE OF AMMONIA.

BY HARRY NAPIER DRAPER, F.C.S.

When paper, which has been floated upon a solution of prussian blue in a saturated solution of oxalate of ammonia, is exposed to the action of light under a negative photographic image, those parts exposed to its influence acquire a faint blue colouration. If the paper be now washed with water and then immersed in weak hydrochloric acid, this slight impression becomes very intense. The excess of acid being now removed, the paper dried and again exposed to light, the image soon fades, but is restored by being kept in darkness.

I have not had leisure to work out any more practical results from this interesting action, but it seems possible that it might be advantageously applied in calico printing, and I have no doubt that little difficulty would be found in forming some black or dark brown iron compound on the blue surface. In this case, quite a new method of photographic printing might be based upon it.

SOME NOTES ON POSITIVE PRINTING.

BY SAMUEL FRY.*

Having gone rapidly through the details of the printing process, I will briefly consider the circumstances which may call for departure from or variation of any of the ordinary methods of manipulation. First in order must assuredly come the different character of negatives which may be operated upon, one may be a dense old fashioned pyrogallic landscape, with a sky, to the delight of some, as "black as your hat;" then a poor, weak, grey image of half tone, perfect in detail, but without high lights or any contrast of light and shade; surely these two negatives should not have their proofs produced by the same details of manipulation. Examine two prints produced from the same negative, the one by a beginner, the other by an accomplished printer; it would scarcely be credited that they were from one plate: difficult, tedious, perplexing as are the steps by which the photographer gradually acquires power over his camera and collodionized plate, I really believe that it requires more patience and practice to print properly. How often have I examined the negative of a painstaking, undaunted amateur in quest of the cause of his miserable prints, and found that the fault lay solely with his printing manipulation, the negative being of fair average quality. Some say that they cannot obtain sufficiently glazed paper, the objection is ridiculous, for some of the finest prints I ever wish to see are on plain paper, toned by carbonate of soda and gold; I can imagine nothing better suited for portraits to be framed, and therefore give the recipe.

I prefer Rive or thin Saxony paper, salt by immersion for 10 minutes in

Chloride of Sodium	1 drachm.
Distilled Water	8 ounces.

* Concluded from p. 423.

Dry by suspension at one corner, and place in a portfolio for use. When required for printing float on a bath of

Nitrate of silver	60 grains.
Distilled Water	1 ounce.

This must be kept carefully in the dark, as it is far more sensitive than albumenized paper. Over print rather more than in ordinary printing, wash out the silver and tone in

Chloride of gold...	1 grain.
Carbonate of soda	2 grains.
Water, 65°	6 ounces.

The action of the gold is most vigorous, and some promptitude is required to prevent the print becoming blue, when a rich violet is attained, wash in cold water, and place in

Hypo	4 ounces,
Water	1 pint,

and in this bath the print acquires magnificent tones, the purest pearly white, and altogether the appearance of a fine engraving on India paper. Now I do not ask any one to relinquish the use of albumenized paper, no one admires it more than I, but for many bold subjects the above process give most exquisite tones, and leave nothing to be desired.

And now to consider the relative virtues of the toning baths which have been recommended, of acetate or carbonate of soda in conjunction with gold. I much question if the former have had its fair trial, or I certainly think it would be in more general use. It has a great advantage that no spontaneous decomposition of materials takes place by keeping the mixture within reasonable limits, and therefore after use nothing but additions of gold is required to keep it in working order for use at any required time.

Chloride of Gold	15 grs.
Acetate of Soda	$7\frac{1}{2}$ drs.
Water	1 quart.

This preparation, suggested by an excellent and careful experimenter, Mr. Hannaford, in my experience gives admirable tones, and only within a few days Mr. Leake, whose portable tent for out-door work is well known, has informed me that he now uses it in preference to other methods, as giving invariably brilliant fine tones and clearness of picture, for an amateur only producing a small number of prints it seems admirably adapted.

The carbonate process, which is the modification more generally used, is simple of preparation, but requires to be freshly mixed on each occasion from precipitation of the gold. A solution of chloride of gold should be made of 1 grain to a drachm of water, and a solution of carbonate of soda of 5 grains to an ounce of water; take 1 drachm of gold solution and add 6 ounces of distilled water, and then add carbonate of soda until neutrality, as indicated by test-paper, is produced. With a given sample of chloride of gold, having observed the quantity of carbonate solution necessary to produce neutrality, the same quantity may be added with safety on subsequent occasions without the trouble of testing, but when a new sample is obtained, go through the litmus paper trial again, as the quantity of free hydrochloric acid varies with every sample of gold. Here I may observe that we have in our power a valuable agent for reducing the over intensity of prints accidentally over printed, as by adding to the solution used to tone such pictures, an excess of carbonate they may be very greatly reduced.

In gold toning but little difficulty is ever experienced in printing large sized negatives containing much detail, and with good vigour, from these plates prints are obtained such as could never be approached by "old hypo," but it is in carte de visite and stereoscopic pictures, that the difficulties of alkaline toning commence; then we see mealy red spots of untoned picture, varying from a pin point to great streaks, and in the attempt to tone them, the pictures which display these faults are almost always dull and grey from prolonged exposure to the gold; I believe these spots are caused by the unequal absorption of the paper from the inequalities of fibre. at one part the albumen rests as a little hillock on the surface, and thus dries; at an adjoining spot again it sinks deep into the surface; can these two surfaces produce the same photographic effect? Not with a rapid toning process, under the "old hypo" regime all this was unknown from the slow, gradual change of silver for gold in the process of toning, but now we do it all in a few minutes. I am free to confess that when I have been tormented with these wretched spots, my only remedy has been to get another sample of paper; this is not flattering to one's vanity, but though certain remedies proposed have lessened the evil, they have not removed it.

Alkaline toning must undoubtedly raise the quality of our negative, for it is essential that they have that contrast of tone which alone produces fine results. In my own practice I keep two sensitizing baths for different qualities of plates, one of 65 grains for ordinary good plates, and one of 90 grains for poor, weak, grey films; these latter we print on the most highly glazed paper, with the strong bath, and a weak light, and then obtain often far better result than might be anticipated.

I will conclude with two wrinkles, neither of my own origination, but both valuable. If your paper curls up when placed on the sensitizing dish, breathe on it, within two inches distance, it will go down instantly. Again, when your finished prints are dry, pour the final washing, roll them up, albumen side *out*, on a stick, in ten minutes all their inclination to curl is gone, and they become as flat as a sheet of note paper.

Critical Notices.

THE LADY OF SHALOTT. By H. P. Robinson, Leamington.

A contemporary critic recently complained that all the erse writers of our day are under the spell of the laureate, that they have got intoxicated with Tennyson, and gone reeling off to follow this new Ariel and his enchantment. "His muse and his music," it is remarked, "are alike irresistible. Some may stop their ears, and bind themselves, Ulysses like, to the mast of their own vessel: it is all in vain. The syrens draw them ashore, vessel and all, and they are wrecked. Shakespeare did not tyrannize over the Elizabethans half so much as Tennyson does over the young mind of the present." That which, however, might be a vice, leading only to feeble imitation in the young poet, may be in the artist a merit, leading to creation. It is no derogation to the imagination of the painter that he should catch his inspiration from the poet, to whose conceptions he endeavours to give pictorial embodiment, thus becoming an "interpreter in the Laureate's own House Beautiful."

Mr. Robinson is amongst those who have drunk inspiration at this fountain. His illustration of "Elaine" we recently noticed briefly, and at the same time referred to a larger and more ambitious work, rendering another scene from Tennyson. The subject is described in the following lines from "The Lady of Shalott."

"Down she came and found a boat
Beneath a willow left afloat,
And round about the prow she wrote
The Lady of Shalott.

"And down the river's dim expanse—
Like some bold seer in a trance,
Seeing all his own mischance—
With a glassy countenance
Did she look to Camelot.

"And at the closing of the day
She loosed the chain and down she lay;
The broad stream bore her far away,
The Lady of Shalott.

"Lying, robed in snowy white
That loosely flowed to left and right,
The leaves upon her falling light,
Thro' the noises of the night,
She floated down to Camelot.

"And as the boat-head wound along
The willowy hills and fields among,
They heard her singing her last song,
The Lady of Shalott."

We know very well that there are many non-photographic and some photographic readers who will smile with complacent pity at the notion of giving embodiment to an imaginative work by means of photography, and regard it as a task more difficult than "making bricks without straw." The task is difficult; and we honour the man whose ardent love of, and faith in, his art, gives him courage to attempt to realize thus the conceptions he has admired. The work must be a labour of love; there has been little honour and less profit gained hitherto by such attempts. Artists and art critics have generally been disposed to sneer at what they deem the presumption of a "servant of servants." Even those who should be authorities in matters photographic are often disposed, with a Burleigh-like shake of the head, to whisper "too ambitious;" and the applause of a few, together with that inborn gratification which makes such efforts their own exceeding great reward, are the only encouragements the pioneers in this yet comparatively untrodden walk of art receive. With our views of this subject, we hold failure in such attempts no shame, whilst we hail every success, entire or partial, with unalloyed satisfaction.

We regard it as one element of success in this picture that Mr. Robinson has caught much of the spirit of mystic solemnity which characterizes the poem. The background of fine old willows, whose branches and foliage, interlacing and overhanging the stream, almost shutting out the light of day, are reflected in the water, pre-Raphaelite in their detail, yet communicating an effect of sadness, sympathetic with the spirit of the incident. Without analyzing his sensations or ascertaining their source, the beholder is impressed at once with a similar sensation of undefined gloom to that conveyed by the poem. Extended in the boat with dishevelled hair and glassy countenance, the "lady" bears out the same idea.

But for two or three faults of detail, which mar the picture on submitting it to critical examination, we should have regarded this as the finest imaginative photograph we have seen. A photographic contemporary has described it as lacking "poetic grace," observing that "this is not the lady for whom the knights came riding two and two.'" We fancy there is some odd misconception here; poetic grace, we imagine, is not exactly the idea intended to be suggested; the whole idea of the poem is gloom, mischance, and sadness, together with an all-pervading mysticism. Not for her come the "knights riding two and two," any more than for her come the

"troop of damsels glad,
An abbot ambling on a pad,
Sometimes a curly shepherd lad,
Or long-haired page in crimson clad."

It is declared that "she hath no loyal knight and true," but is a picture of desolate loneliness. Poetry there is in the picture, but it is certainly not, nor should it be of a graceful character; gloom is rather its chief suggestion.

There are, as we have said, some few faults in the picture, but these are of a quality which detract rather from its truth than from its imaginative beauties. A gentleman of much taste remarked, of it to us whilst examining it in the Manchester Exhibition, that "the boatlooked somewhat wooden." Of course a boat is wooden; but the remark was suggestive of the fact that the character which should indicate the form rather than the material, was absent. From under-exposure, we presume, the reflections which should be thrown by the water on the underside of the boat are not rendered, and the only means of showing its form are lost, the effect being of a flat profile, rather than the convex lines of a boat. Much more detrimental to the truth than this, however, is the absence of any appearance of motion. A boat gliding, however gently, down the stream, would in dividing the water cause slight eddying wavelets, which catching the light would at once give some effect of life and motion to the water. The broad leaves of the water-lily, would in like manner, slightly disturb the glassy smoothness of the surface, causing little rippling circlets and undulations, with light glancing from their rising edges. These ripples and eddies would disturb the perfect form of any reflections in the water. Here, however, the boat is reflected almost as perfectly, as regards form, as in a mirror. We presume the fact is, the boat was taken in still water, and when quite motionless; but if we were hypercritical, we should say it has almost the effect, from the boat not being sufficiently deep in the water to suggest the idea of floating, and from the cause we have named, of being laid on to a mirror rather than floating in water. The dim twilight effect of the close of a dull day is well preserved generally, but is slightly marred by the too vivid patches of light on some parts of the river.

There is another point in which Mr. Robinson has missed somewhat the spirit, and even the letter of the description. The idea conveyed in the poem is of entire abandon.

"Lying robed in snowy white,
That loosely flowed to left and right,
The leaves upon her falling light."

In the picture we have not the snowy white robe flying to left and right; a little white drapery is to be seen gathered closely round her bosom; but the figure is well covered and "tucked in" with some dark damask drapery. This may contribute to the effect of the picture in one sense, but it detracts from the truth of the description, and destroys the idea of abandon conveyed in the drapery flowing to left and right, with the falling leaves scattered lightly upon it. At present the dark drapery is almost necessary to relieve the figure against the light on the water; but we imagine the effect might have been much finer, if it had been so managed that the figure was the sole focus of light; the river, as well as all the accessories being kept in shadow or half tint.

It will be observed that we criticize this picture rather as work of art than as a photograph. Such pictures demand a high standard of criticism; and we unhesitatingly say that we have known many Academy pictures obtain much praise that had not a tithe of its merit, either as regards poetry or truth. As a whole we regard this as a noble picture: it is finely conceived, and for the most part well worked out. Had we admired it less as a work of art, we should not have cared to criticize minor faults, and it is only because the picture is so fine in other respects, that these faults of detail are worthy of notice. Mr. Robinson aims high, and often succeeds well, and we shall look with pleasure for more in this direction rom his hands. The production of one such photograph we regard, however, as sufficient to stamp a man an artist, and his work fine art. The picture is about 20 inches by 13 inches, and is, we understand, from three negatives. For the most part the photography is excellent.

THE ART CLAIMS OF PHOTOGRAPHY.

[We have selected from the various replies to "R. A." on this subject, four letters, from what may be termed "representative men." The first, M. Claudet may be just regarded as, in a double sense, one of the first photographic portraitist in the world. The second is from an artist, that is a painter; the third from an amateur; and the fourth from an operator. Other correspondents who have written on this subject will see that their arguments are already employed in the letters given, and that our space precludes mere repetition.]

Barbarus ego sum, quia non intelligor illis.

Sir,—In a recent number of your journal a correspondent under the initials of R. A., taking for epigraph "audi alteram partem," has endeavoured to prove in a letter more elegantly written than logically thought, that photography is not a *fine art*, that the Commissioners of the Great Exhibition have acted wisely and justly in classifying it in the mechanical department, and that the Photographic Society has assumed very absurd and preposterous pretensions in daring to take up the dignity of the body it represents.

The point in discussion rests entirely on the sense which ought to be given to the term *fine arts*, and as in all discussions the main thing is to agree upon the meaning of the words employed, let us first endeavour to determine that important question.

The expression *fine arts* appears to be of very recent introduction in literature. In Johnson's Dictionary there are many paragraphs devoted to the various applications of the word *art*, but not the least allusion is made to the term *fine arts*.

The "Dictionnaire de l'Academie Française," is not more explicit. The word art is expounded in various acceptations, but there is no mention of *Beaux arts*. The "Dictionnaire universel de Bouillet," Paris, 1854, has the words Beaux arts and explains them thus:—"*Beaux arts*, on réunit sous ce nom tous les arts qui ont pour but de charmer les sens par la culture du beau, les arts du dessin (peinture, sculpture, gravure, architecture) la musique, la danse."

"Crabb's Technical Dictionary," London, 1851, does not give the words fine arts, it merely distinguishes the liberal arts from the mechanical arts, and has—"*art*, from the Latin *ars*, and the Greek *aro*, to adopt. The contrivance and disposal of things by help of thought and experience, and according to prescribed rules. The *liberal arts* are those which are noble and worthy to be cultivated without regard to the lucre which they may bring, such as architecture, grammar, music, painting, poetry; and the *mechanical arts* are those wherein the hand and the body are more concerned than the mind, which are followed for the sake of the gain that accrues from them."

Maunders' "Scientific and Literary Treasury" has:—"*fine arts*, a term somewhat indefinite in its meaning, but generally applied to those arts which depend on the mind and imagination, opposed to *mechanical*."

Maunders' "Treasury of Knowledge" defines *fine arts* thus: —"The arts which are the growth of taste and refinement, as poetry, painting, &c."

According to Bouillet, if the *fine arts* are those which have for aim to charm the senses by the cultivation of the beautiful, such as the arts of drawing (painting, sculpture, engraving, architecture), music, and dancing; surely photography so highly capable of cultivating the beautiful, ought to be classified among the fine arts.

If, according to Crabb, the liberal arts are those which are worthy to be cultivated without regard to the lucre they may bring, in this exalted point of view, is it not right that photography, practised by royalty and aristocracy, should be ranked among the *liberal arts*, and not among the mechanical arts, wherein the hand and the body are more concerned than the mind? Certainly the scientific art of photography, in which the mind, thoughts, and taste, have so much to do, cannot be called a purely *mechanical art*.

If we adopt the sense given to *fine arts* by all the above authorities, this sense seems to mark pretty clearly the place belonging to photography. We must at the same time acknowledge that among the arts called fine arts, there are some which are much nobler, more perfect, and more refined than others. No one will pretend that engraving and dancing require as much thought, genius, and knowledge, as poetry, painting, and sculpture; still it is generally agreed that *engraving* and *dancing* are sisters to the *fine arts*. Why should the younger and promising sister, Photography, be repudiated or scornfully treated by her elders, who have so much to learn from her, and who have received already at her hands more than one useful lesson.

The ancients in their mythology had personified the arts. Nine Muses represented the various forms under which the mind exercises its most refined aspirations and charms by its intellectual power. Apollo, the god of all the arts, was the patron of the muses, and he changed the ears of Midas into those of an ass for having dared to suppose that Pan was superior to him in singing and playing on the flute. A great lesson, that we must not forget in the fear that our ears should suddenly expand into an unenviable dimension, and even photographers would well deserve the punishment if they had the imprudent audacity of putting their art above or on the same level as painting and poetry. Their pretensions are more modest, although dignified. Photography, born the last, claims a seat, at least a stool, in the temple of the *fine arts*.

How is it that the ancients had no muse either for painting or sculpture? In the primitive ages were painting and sculpture classified in the mechanical arts, as considered not deserving to be admitted in the great temple consecrated to the liberal arts? If it were so, photography in its infancy should not complain of a similar treatment. But let us try to find a more natural cause for the omission.

It must be supposed that the arts of painting and sculpture were flourishing only long after those which were personified by the nine muses. This supposition is very plausible when we think that poetry, history, tragedy, music, dancing, lyric poetry, singing, rhetoric, eloquence, and astronomy, must have been the first refined occupations of the mind. Men thought, spoke, loved, sang, danced, recorded past events, imitated terrible and mimic deeds, before they were led to imitate natural forms by cutting stones or modelling clay. Painting, more complicated and difficult than sculpture, was the result of a higher state of civilization. It required the invention of various pigments, a considerable skill in their proper application, and much judgment in the appreciation of the effect they produced.

Before painting was sufficiently perfect to be considered as an art, ages were to elapse in total ignorance of its powers. Painting came long after the epoch when men, being congregated in society, turned their thoughts towards a system of religion, when in their ignorance they could not do without a distinct God, supposed to superintend every separate work of the creation, to regulate every branch of human intellect, and to watch over each of their individual wants. Then we can understand why mythology did not include painting and sculpture in the arts represented by the Muses, for these arts had not yet been discovered or recognised.

Therefore, the fact that painting and sculpture in those times had no patrons in mythology, cannot in the least make us believe that these two beautiful branches of the *fine arts*, had been discarded in the estimation of pristine society. The ancients merely were as much ignorant of the capabilities of the mind to embrace the powers of sculpture and painting, as subsequent civilizations, when these arts had been flourishing and acknowledged as branches of the *fine arts*, were ignorant of new branches which science and the wants of a more advanced state of society were to create for the improvement and enjoyment of mankind.

Painting and sculpture for ages had no seat in the temple of the arts, would they now illiberally in their trumph, forgetting their long abandonment, refuse to photography the rank in the *fine arts* generally accorded to engraving and dancing.

Royal Academician (as I interpret your initials R.A.), don't be too proud and exclusive, photography deserves your respect on account of its noble and marvellous origin, and your gratitude for the services it has rendered and is destined to render to all the fine arts. Be just towards the sister art, who is the great teacher for all, who accustoms the eyes of the public to discern what is correct and what is false in composition, drawing, and perpective. Has it not been observed that since photography is constantly infusing in all classes the taste for artistic knowledge, the visitors of picture galleries are now readier to notice in the works exhibited the least fault of proportion, which before they would not have been able to detect. Photographic productions are in the hands of every one, and the eyes accustomed to their *mechanical* truth, even if they do not contain the higher qualifications of which they are susceptible, become more and more difficult and competent judges.

You ask—Is photography properly an art or a science? and you grant that to a *certain extent* it is both, although more properly the latter than the former. I answer that if it is more a *science* than *an art*, it does not prove that it is *not an art*; on the contrary, the science enhances the art, and from that singularly fortunate union, is derived in the fullest acceptation of the words a liberal art and *fine art*.

One of the strong arguments by which you attempt to lower photography, is that it depends from first to last, for the production of results, upon a series of chemical reactions. That the tyro in photography is recommended first to gain some knowledge of chemistry in order to attain excellence in his operations. This is perfectly true, and I may add that the tyro in painting or sculpture need not trouble his head to endeavour to acquire much scientific knowledge; but a little reflection will show that a complete study of chemistry would be exceedingly useful to the painter, to teach him how to make his colours, and use them according to scientific principles, so that by the laws of affinity they should not act injuriously one upon another, or be affected by the persisting action of the gases mixed with the air, and by all other meteorologic, hygrometric, calorific and actinic influences. Another difficult study, that of optics, would enable him to understand thoroughly the laws of perspective and proportion of objects according to their distances; the principles of binocular vision as they were comprehended and explained by Leonardo Da Vinci, showing that as pictures are painted in one perspective (that given by a single eye) they should be examined only with one eye in order to present to our perception, in a greater degree of truth, the natural effect expected in the picture. The singularity of this fact is not understood by all eminent painters, and while conversing with them on this curious question, to my great surprise, I have found many denying the truth of the assertion, or not having the least notion of its meaning.

However, the painter without the least knowledge of chemistry, relying for the production of his pigments, upon the honesty and science of others, and without knowing the principles of optics, is still capable by following empirical data to exercise his genius and artistic taste. The photographer has not the same advantage, he cannot realize any intellectual conception, his mind has no power, and as the poet says,

Pour lui Phœbus est sourd, et Pégase est rétif,

if his chemicals are *out of order*, his lenses and camera in *bad condition*, or unscientifically regulated.

The necessity for the photographer to acquire many difficult and complicated sciences, do not exempt him from gaining artistic knowledge. But he has to be proficient in the *mechanical art* of photography before he can think of becoming proficient in the fine art of photography.

All the various applications of the *mechanical art* of photography can, in a greater or less degree, exercise the genius, the taste, and judgment of an artistic mind, but it is in the application of photography to taking portraits that there is room for the greatest effort of intellect, and the greatest display of talent.

The portrait photographer must in the shortest time possible place his sitter in a natural and graceful position, without the least appearance of affectation. He must see at a glance the best arrangement of the dress and draperies, avoid hard contrasts in their colours, light the head and the whole body in the most favourable manner.

Hæc amant obscurum volet hæc sub luce videri.

If some features are imperfect, a certain position given to the head may improve the effect. He has to attend to the expression, and while conversing with the sitter, to discover and seize the moment when the eyes and mouth appear in repose, and express refinement.

The photographer who understands his art has to hide all the defects, and to show more pre-eminently what is beautiful and perfect; in one word, he has to compose, as much as possible, a pleasing picture, and if he be a real artist, he can generally succeed in the attempt, at all events if he fails, he will never show the result, proving by the concealment of the bad, as much taste as by exhibiting the good results.

Will you deny that the photographer who can produce pleasing and artistic portraits is not practising a fine art? No, you say yourself that you have seen many *photographs perfect gems of art*, and thus photography in the hands of a true artist may often yield results worthy to be *classed as works of fine art*. But you add all this is due to the man, not to the method. Is it not the same in painting, in sculpture, in any art; are the gems due to the man or to the method? Do you pretend that every work produced by the methods of painting and sculpture are works of fine arts? I say, that the greatest number are rather works of ugly art, than works of fine arts. So it is in photography, and more than in any other art. But can there be anything more horrid than bad painting and bad music? Because, as you have observed very rightly, there is not one per cent. of those practising photography who have any claim whatever to the name of artist, or who have had any art training or education; you conclude wrongly that photography is not a *fine art*. What strange aberration of reasoning! Because not one in a thousand who sing, dance, and use a musical instrument, have not the least notion of the arts of music and dancing, does it follow that music and dancing are not *fine arts?* Because not one in a thousand (I do not exaggerate) who paint in oil or water colour, or draw in crayon, have the least knowledge of perspective and drawing, and know anything concerning the right application of colours, does that prove that painting is not a *fine art?*

How can you impute it as a reproach to photography that those claiming the name of photographic artists have left the farm and the merchandise, and even less dignified callings, to take up the camera? Among them you willingly admit the existence of many men of eminently artistic capacity and taste; but those again are the exception, not the rule. I admit the truth of your assertion, and I deplore the fact more than you can. The generality of those who claim the name of photographic artists indeed are uneducated and incapable of producing results with the least feeling and taste. But whose fault is it? certainly not that of photography. It is the fault of the public who, not understanding or caring for what is good and what is bad, encourage the libels on the "human face divine" by giving occupation to those inept and vulgar workers at photography. But has not this been always the case? before photography, did not the same ignorant and barbarous public give work to those painters who were a disgrace to the art? This cannot be helped; and, besides, is it not in some respects fortunate that the poor could have his photographic portrait for sixpence? The humbler classes do not care much about refinement in art; they are satisfied with a likeness which at all events has a certain degree of correctness, and is far superior in truthful individuality to the portraits executed at some expense by very inferior miniature portrait painters.

What is the conclusion of all this discussion? If you have not proved that photography in the hands of men endowed with taste, feeling, and refinement, cannot produce results which charm the senses, by representing what is beautiful in nature—that they cannot stamp their works by some effort of mind—you have failed in your attempts to disparage photography, and to repudiate it as one of the *fine arts*.

The great cause of misunderstanding and confusion in this discussion is, that when one speaks of *fine arts*, one thinks only of such names as Raphael, and Michael Angelo, and he forgets that there has been produced, and are produced, disgusting paintings by the same art, and by the same method employed by Raphael and Michael Angelo. In speaking of *fine arts*, one thinks only of Poetry and Painting, but one forgets that there are some humbler arts which are also called *fine arts*. Photography, the accomplished daughter of Science, may enter in the circle of the Muses, between engraving and dancing, as far as you like of painting and poetry. But she must be in the circle.—I am, sir, your obedient servant,

107, *Regent Street*, 11*th September*, 1861. A. Claudet.

AN ARTIST'S REPLY TO R. A.

Dear Sir,—For an evidently prejudiced man, your correspondent "R. A." displays no little candour and good sense. I am heartily glad to find his letter in my "this week's News," because I anticipate that so clear a statement from one side will not fail to meet with a no less clear refutation—either from yourself, or from some of your able and excellent writers on photography as a fine art. Without venturing to anticipate such able friends, I should nevertheless like to add my mite of a contribution on the subject.

In the first place I willingly admit the facts R. A. advances as indicating the hitherto general recognition of photography as purely scientific. I know very well that the art *does* depend "upon a series of chemical reactions,"—that the education of the photographer for its professional practice *is*, from beginning to ending, avowedly scientific—that artistic failures are almost entirely ignored; and that the only failures generally recognized are those due to defective chemical, optical, or manipulatory conditions. I know also that all our accepted authorities are great in the scientific rather than the artistic, that while the dictates of eminent artists have been pooh-poohed at the meetings of societies, the veriest tyro in science has claimed a respectful hearing: nor am I going to deny "that the professional photographer generally relies for success upon the purity of his chemicals, the perfection of his lenses, and his skill as an operator." But admitting all this, what on earth has all this to do with the question in hand?

If brushes and palettes constituted a fine art in themselves, then R. A. might say photography is not a fine art, because its productions are obtained by the use of no such things. If the education of the photographer is purely scientific, this fact *itself* accounts for the want of artistic qualities in his productions, and is far from an argument against the art's want of artistic capabilities. If only one class of failures are recognized, while, as R. A. admits, others exist, it is evidence against the professor and not against his art. If all our accepted authorities are great in the scientific rather than the artistic, R. A. must remember the art is based upon a science, and that its first and most urgent necessities arose rather from scientific than artistic shortcomings. In short, if R. A. wants to *prove* that a certain branch of science is not capable of being cultivated as a fine art, he must do something more than show that it has not, up to the present time, received its fair share of such cultivation.

In the next place R. A. asserts that the various degrees of merit shown by photographs do not prove photography to be a fine art, because such differences may be found in the productions of arts purely and avowedly mechanical. Very true; but neither do such differences *dis*prove the claims of photography to a position among the fine arts: while, if it is shown that such differences can to a very large extent be traced to the presence or absence of intellectual artistic acquirements, rather than superior appliances, or different degrees of mechanical ability, I then think such differences *do* certainly go a long way in proving my views of the matter.

As to the mirror illustration, and the insinuation that the photographer has no more right to be called an artist, because his silvered glasses reflect and retain the images of nature, than the man who silvers the glass of a mirror to perform a similar feat,—pray, will not the same argument tell against every branch of imitative art, and deny the title of artist to Claude, Raphael, Wilkie, and a host of other great painters, including all the fine masters of the Dutch school, whose works are as strictly imitative as those of the photographer? How many a great painter has yearned to depict a beautiful scene with all the fidelity of a mirror; but did this prove him no artist? Did Shakspeare recommend the actor to "hold the *mirror* up to nature" because he would thus *degrade* his art, or because truthfulness was its loftiest quality? Truly, R. A., I do think you are grievously wrong in your arguments against the position claimed by one of the greatest and most wonderful powers of our great and wonderful age.

Now the reluctance with which the claims of photography, as a fine art, are met, seems to meto be due not to any want, or defects, or peculiarity of the art itself, but rather to the loose indefinite ideas associated with the term, "Fine arts." The word "*Art*" undoubtedly has a wide significance; we understand what such a word means, and know, that although it excludes numerous branches of subordinate industry, it still embraces a vast multitude of trades and callings associated with civilization and intellectual advancement. But when we pick out certain arts and call them "*fine*," pray what new significance do we derive from the appending of this last unmeaning word? "Oh!" says one "it means painting, sculpture, architecture, poetry, and music." "No," says another, "it only means painting and sculpture;" and "no," again says another, "it means painting and poetry." Who shall decide? the term *itself* signifies nothing at all, and we can only define an art by its conventional and descriptive title, when it embodies such demands as are responded to by other arts to which such a title is universally awarded. Judge photography *thus*, and it is a fine art. I leave the elaboration of such arguments to more able hands, and am, dear sir, yours obediently,

September 7th, 1861. R. A. S.

AN AMATEUR'S ANSWER TO R.A.

Magna est Veritas et prævalelit.

Dear Sir,—It seems the prevailing idea among the depreciators of photography, that it aspires to the highest place among the arts, and that if it can be shown to be wanting in any of those fine qualities that dignify its sister arts, it falls entirely out of their sphere. Your correspondent "R. A." is conspicuous in the foremost rank of these assailants, and in debating the question, how far photography is a fine art, appears to lay great stress upon the assumption, that its followers exhibit great ignorance, not of the principles of light and shade, nor in the art of grouping their figures, nor in the general composition of a picture, but in the knowledge of the mind of man and his motives, and in winding up his dissertation he again and again triumphantly puts the very pertinent question, Do photographers show a knowledge of human nature?

But as in the arts one requires different qualifications from another, so in each there is room for the exercise of different kinds of talent. A man may establish his claim to be a poet by a sonnet or ballad as well as by an epic poem. The translation of Homer called forth powers of a different kind to those exhibited in the composition of "The Rape of the Lock," but either production would have secured to its author a high place in the Temple of the Muses. So with music, a composer takes the first place, but the performers of his works, whether vocalists or instrumentalists, may be artists also, nor does it invalidate the claim of the latter to the title, that he is dependent in a great measure on the mechanical excellence of his instrument for the beauty of the performance, nor would it alter the case if he constructed his own instrument. Granted that a knowledge of chemistry is essential to a photographer of merit, is not an acquaintance with anatomy requisite for a painter or sculptor, and even with this he calls in other appliances to his aid? Does anyone suppose that the figures in the group are dashed off from the teeming brain of the artist without careful and often servile copy from a living model? Is not chemistry invoked to produce and render permanent the colours of the painter, and is not digital dexterity needful in laying the colours on the canvas? It is true that the photographers is bound by more than ordinary strictness to his subject, but nature may be viewed in as many different aspects as painters view their models, and the result in either case would receive the "impress of the mind of the artist."

But is it reasonable or manly to lay such violent hands on infant photography, of giant growth though it be? While painting can count its age by hundreds of years, photography can number but units yet so great has been its progress, that people think nothing beyond its reach, and quarrel with its tardiness in reaching perfection. Good people, have as much patience as the artist who labours untiringly through more difficulties than you dream of. Though our pictures have no colour yet the advance of our art hitherto promises it. Though iodine and bromine have not yet yielded up their secret treasures, has not fluorine given ray for ray to the searching developers, and what photographer does not look forward with confident expectation to the time when his pictures will glow with nature's own tints, which though snatched somewhat rudely will not be an unwelcome exchange for those gaudy and tattered garments of conventionalism with which the necessity of her needy admirers have hitherto clothed her.

Surely, sir, in this age, those who wander side by side through the paradise of nature ever intent on finding and securing those beauties which will lavish hands, she has for all and to spare, ought to be more liberal to each other than to assert that because one art attains its end by particular means, any other process is disqualified from sharing the honour with it. The remarks of "R. A." amount to this, "You must not use a lens and chemicals, but you must use a pencil or a brush; it is of no use that you are a skilful manipulator, but you must be dexterous in the use of your pencil; and although it be true that the lens and chemicals *will yield in the hands of a true artist works worthy to be classed* with those produced by the pencil, this merit being *due to the artist and not the method, i. e.* independent of the means employed, yet *you* must not be independent, and use your lens, but use your pencil as I do."

However loth photographers may be to succumb to this conclusion, the most enthusiastic will not differ from R. A's. premises. Perhaps we should agree still more with those whose sentiments R. A. represents, did they recognise more fairly the difference, not in degree, but in kind between good and bad photography. They expect this treatment from their opponents, if indeed we are to be so termed, and would loudly exclaim no doubt against the injustice of their art being held responsible for the quaint inventions of the sign painter.—Yours truly, M. A.

AN OPERATOR'S ANSWER TO R.A.

Sir,—In a recent number, I noticed a letter (The Art Claims of Photography), upon which I wish to offer some remarks, if I may be permitted to do so.

As your correspondent "R. A." seems to despise photography in connexion with fine art, let him know in the first instance that it is useful, I may say necessary, to a great many artists. Could the paintings in the forthcoming Exhibition speak for themselves (I do not mean any harm), we should soon know how many of them have been got up without the aid of photography.

I will now go further, and touch upon the invidious distinction drawn between painted portraits and photographic portraiture; the former "R. A." calls fine art, the latter he terms what? why "the very apotheosis of the common-place and vulgar."

Where "R. A." got his notions is more than I can tell, but he must be the son of a genius (or perhaps a genius himself) to adopt such a flowing style, and has every right to rank as belonging to fine art.

The inconsistency of his remarks is, however, easily proved by a single glance at the hundreds of cartes de visite now extant of the most remarkable and leading men of our day.

We will now examine the difference existing between the two styles of portraiture; at the outset there is one point on which I must agree with "R. A.," he is certainly correct in saying that chemistry is a science, and cannot be called art; hence it follows that neither the theory of colours, nor the effects produced by their contrast, or by their harmony, (so beautifully illustrated by Mr. Chevreuil, chemist at the dye-works of the Gobelins), can not be called art, ranging as they both do within the science of chemistry.

Art consists then in drawing lines, and in the application of black and white pigments in certain places to produce lights and shadows.

We must then infer that a portrait painted in sepia, or white and black, has the same merit as one painted in colours, and is quite as artistic in every point of view.

The painter adopts certain means to obtain a desired result.

We photographers adopt other and different means, but the study of light and shade, the pose effects, draperies, etc., require in both, the same skill and artistic talent. We do not, and ought not, to regard the means employed in obtaining such a result, so long as they are not purely mechanical.

The camera-obscura has long since been employed by eminent artists; science discovered the means of fixing and producing the picture which the artist used to copy from the ground-glass to transparent paper, doubtless a severe blow was thus dealt to many, especially to those always unwilling to acknowledge progress; some were deprived of the prospect of future reputations, others even of their livelihood, and I can understand to a certain extent why photography is despised by those who have thus suffered.

I nevertheless contend that a good photographic portrait possesses the same merit as any other, and I do not see why a portrait painted on canvas should rank among specimens of fine art, while a life-size photograph, far superior in every respect, should be classed with a roasting-jack or a knife-cleaner.

Photographic landscapes are literally copied by artists, and with the introduction of a figure or two, painted in water-colours, and exhibited as works of fine art. Surely no further comment is needed on this portion of our subject, enough has been said to vindicate the superiority of photography.

Next comes composition; on this subject I will be very modest, as you will acknowledge when you learn that I intend seeking composition, not only in Rejlander, but even in the humble stereoscopic slides, how many little gems do I find amongst them. I have seen hanging on the walls of the Royal Academy, groups or composition not to be compared with them.

But after all we belong to the progressive school, what do we want with composition?

Cannot we take instantaneous views,—man in the act of falling, horses galloping, clouds, waves, multitude, or masses, with the right expression on every face, joy and sorrow, tranquillity and agitation, to say nothing of celestial bodies; what more do we require? How can all this be successfully depicted save by the aid of photography?

Again it is said photography cannot modify, cannot imagine, cannot create. We do not want to modify, nor create, nor imagine; our art is not rich in deception or illusion, our aim is to study and to copy nature.

Fine art of the present day does more than modify, it transforms according to the pride of the person who pays for his vanity.

The Raphaelite school, the most true in proportions, is forgotten by many modern artists.

Certainly photography has its caricaturists, but has not fine art also its worthies with whose productions Jones's auction-rooms and others are crammed every week? I do not make comparisons in an offensive or insulting sense, but merely to show that people who despise photography on account of the vulgarity, have looked only on one side of the illustrative shield, and that photography, although strangely mutilated, ought not to be looked upon with such contempt and indifference by those who have reason to encourage it as a science and art.

Then again it is said, leading men in photography are not artists, they are chemists, mathematicians, &c. We know that photography is an art combined with science; science is the leader of all improvements, thanks to scientific men, photography has in a few years made considerable progress, and by becoming popular has imported to a certain class of people more real knowledge of art, than fine art has done in centuries. Photography has by its faithful reproductions made people intimate and familar with all that is beautiful and grand in nature.

What would have been the result if leading men had been like your correspondent, the slaves of fine art? Why photography would have remained stationary; artists contented with the comera-obscura, relying on their skill to copy the image given on the focussing screen, would have found the early daguerreotypes sufficient to convey their ideas to paper or canvas.

We must certainly admit that there is less selfishness in science than in fine art.

If scientific men have found a mean of drawing by light, with the aid of talented men, more correctly than any artist (whoever he may be), with all his brushes and pencils, then I exclaim that science has done for fine art what the steam locomotive has done for the old mode of travelling.

Is it not plausible, rational and just, that photography, connected so closely with nature in scientific researches and all artistic combination, should rank with fine art, rather than be termed mechanical, and classed as such?

Let the Commissioners be very particular in admitting only what is really *good* and *artistic*, and I think gentlemen of fine art, like R. A., will have nothing to fear about vulgarity; and unless such course is adopted, I think, for my own part, that it will be better for any photographer really possessing some artistic notions, to retire from the field of competition, whatever may be the consequence.

Let those who think photography purely mechanical exhibit some specimens taken by their own process.—Apologising for the trouble, I am yours, obediently, H. A. B

London, 11th September, 1861.

British Association for the Advancement of Science.

THE PANORAMIC LENS.

[We have received from Mr. Sutton the following authentic MS. of his paper on the panoramic lens, read before the British Association, on Thursday, September 5th, in Section A.]

The lenses commonly used by photographers for taking views have two grave defects, viz., they give curvature to lines at the margin of the picture which ought to be straight, —and they include too narrow a field of view for a large and important class of subjects. In a paper which I had the honour to lay before the British Association at the meeting in Aberdeen two years ago, I described a symmetrical triple combination of lenses, which was intended to remedy the former of the above-mentioned defects. That combination has been found to answer the purpose, and is now manufactured by Mr. Ross, the celebrated London optician. I now beg to lay before the meeting another and a very curious lens, which remedies the latter of the defects named, and produces an optical image which includes an angular field of 100° and upwards, in perfect focus to the extreme ends of the picture. This lens, which is an entirely new optical instrument, unlike anything else, I have called a "Panoramic Lens," and will now describe.

Imagine, in the first place, a thick spherical shell of glass, having its internal spherical cavity filled with water, and then, since the entire sphere is not required, imagine a central zone of the glass shell removed, and its place supplied by the brass mounting of the lens.

When the above arrangement is fitted with a central diaphragm having a small central aperture, it is evident that the pencils of light which pass through it must be incident perpendicularly upon each of the four surfaces, and therefore there is no such thing in this lens as an oblique pencil, and the errors due to oblique incidence are completely avoided, and the image formed in every part by direct pencils.

The glass shell, being a lens with concentric surfaces, acts as a concave or diminishing lens, and has positive focal length: while the central sphere of water acts as a convex lens, and has negative focal length. The medium having the *highest* refractive and dispersive power, is therefore made into a *concave* lens, while the medium having the *lowest* refractive and dispersive power, is made into a *convex* lens. It is possible therefore to render this compound achromatic by giving a suitable radius to the inner surface of the shell. The investigation is extremely simple, and the practical result very neat and convenient. It turns out that when light flint glass is used the lens is achromatic when the inner radius of the shell is about one half the length of the outer radius. The combination may properly be called a symmetrically achromatized sphere. It is a valuable property of a sphere achromatized in this way, that its focal length is greatly increased, so that a large picture can be taken with a tolerably small lens.

The central diaphragm is another curious part of this instrument. It is evident that if it were merely furnished with a central circular hole, the sides of the picture would be less illuminated than the centre. To meet this inconvenience I have made the central hole elliptical, and have placed in front of it two upright thin partitions, radiating from the centre, and looking like the open wings of a butterfly. These stop some of the light of the central pencil and make it cylindrical, and at the same time they make the side pencils cylindrical also, and of the same diameter as the central one. This simple contrivance answers perfectly in equalizing the illumination, and will be understood by examining the lens which I have sent for inspection.

The image of distant objects, formed by a panoramic lens, lies upon the surface of a sphere which is concentric with the lens. But the objects of an ordinary view are not all distant ones, for the objects upon the ground are generally much nearer to the lens than those upon the horizontal line. It is found, therefore, in practice, that the best form of focussing screen to meet the majority of cases which occur in practice, is a part of a cylinder having the same centre as the lens, and including about 30° below and 20° above the horizontal line. The panoramic picture therefore includes about 100° in width and 50° in height. The upright lines are straight, and the perspective strictly correct in all parts of the picture.

Collodion pictures are taken upon curved glasses, and the negatives printed in a curved printing frame. I have not found any more practical difficulty in working upon curved than upon flat glasses. Everything goes on in the usual way, and the various operations do not occupy more than the usual time.

I am in hopes that the panoramic lens will meet a great want which has long been felt by photographic artists in taking views of natural scenery, since it includes quite as much subject as an artist ever requires in one picture.

I have sent for inspection a complete set of panoramic apparatus, manufactured by Mr. Thomas Ross, and also a negative upon a curved glass, including about 100°, and a print from the same. Thomas Sutton.

NEW DRY PROCESS.

We find in the *Photographic Notes*, which quotes the *Melbourne Argus*, an account of what is termed a *new* dry process; but it appears to be a modification of Dr. Hill Norris's gelatine process. The specimens which were shown to the Melbourne Photographic Society, at a meeting of which the process was described, are described as very good, and bearing favourable comparison with others taken in wet collodion, The following is the description given by Mr. G. M. Hardess, to whom the modification is due:—

"I use common glass—that which is generally known as flatted sheet—which I clean with a strong solution of caustic potash and rotten-stone, freed from all grit. The plate is then well washed, dried and polished with some old collodion. I have used the same plate several times, but have seldom found stains or dirty markings therefrom. The plate is now ready for coating with collodion. I have used collodion of all kinds, sometimes very old and dark coloured from free iodine, but I certainly would not recommend such to be used in general. The collodion should be the best for the purpose, made expressly for a dry collodion process. That which I am using at present is made from good ether and alcohol, of the proper specific gravity, the pyroxyline being the best I could obtain. I iodize with cadmium and calcium, using with these either the bromide of cadmium or ammonia. I have used various proportions, but have not, I regret, been careful to mark the results. For landscape, however, I find generally a third of bromide best. But the iodizing might be left to each operator's judgment. The collodion being poured over the plate, it is sensitized in a nitrate bath of 30-grs. of silver to the ounce, and slightly acidified with acetic acid; when taken out of the bath it is well drained upon white blotting-paper: when well drained, the plate is washed for a few seconds in distilled water, drained, and it is ready for the dry solution, which is made as follows:—Take 20-grs. of Nelson's patent gelatine, soak and dissolve it in 3-ozs. of distilled water (it will be necessary to use heat to dissolve the gelatine); then add ½-oz. of white crystallized sugar, or, better still, pure white sugar-candy. Now take 1-oz. of albumen—the white of a newly-laid egg is sufficient—beat it up, and add two or three drops of liquid ammonia, and when beaten add 2-ozs. of distilled water; mix the two solutions together, and filter sufficient for use through filtering paper; pour it over the plate, drain, and dry, either by spontaneous heat or otherwise. The plate is now ready for exposure—the time will vary much with the power of the light and subject, varying from 90 seconds to 10 minutes, or more. I have used generally an ordinary view lens—Lerebour's—and ½-in. diaphragm. When sufficiently exposed, the plate is washed with water and developed with pyrogallic acid and silver. The development is generally rapid; it is then washed and fixed in the ordinary manner. Failures will doubtless be found, but by careful manipulation and pure chemicals, the failures will be but few."

TESTING COLLODION AND THE BATH.

Photographers who have had considerable experience know that success in making collodion pictures depends upon a great variety of circumstances, and that to control all these requires a great deal of wisdom and executive tact. When everything is in perfect order nothing is easier than success,—a failure is rather a freak of chance. But when one condition of success in a dozen is not present, in what a maze is the miserable befogged tyro. To him a miss is as good as a mile; to him the one screw loose is invisible. How he fumes and rages—to no purpose; he imagines Satan in the collodion, then in the bath, developer, and fixing; he is ready to pitch all out of the window, and finally perhaps himself also. Those who tried to practise the collodion process about the year 1853, will remember such a picture as this was an everyday possibility.

Photographers, however, who have had an experience of many years, have learned how to master the little difficulties which so much bothered them at first. They avoid them by force of habit, almost instinctively, and wonder how it was that they were bothered so much at first.

The most serious and perplexing difficulties with which the practical photographer is obliged to grapple, reside in the collodion or the bath, or the want of congeniality of one with the other, or a complication of all these troubles. And what makes such cases often exceedingly harassing, is the uncertainty as to the locale of the disease. We cannot determine at once if the want of intensity, the slowness or the fog comes from the collodion or the bath.

We would like to have some simple and certain rules of diagnosis, or a diviner's rod, which should at once point to the root of our evils. What a fine thing would be an instrument graduated like a thermometer which would show at sight precisely how much above or below zero our operations are!

There are, however, within our reach, some rather simple and practicable tests for the bath and collodion. These I will point out. I would suggest that there be kept on hand a standard bath and collodion to be reserved and used only for tests. These should be made with the greatest care, and so securely kept that they shall not change. If a collodion is suspected, let it be tested in the standard bath, or if a bath be suspected let the standard collodion be tried in it. When two collodions are to be compared, the most ready way is to coat the same glass with the two collodions, giving each one its separate half of the plate. On making a picture, the minutest shades of difference in quickness, intensity, or brilliancy, are plainly shown to the eye.

I propose the test collodion and bath only for the more expert. Their proper use would require rather nicer discrimination and skill than the tyro would be likely to command.

We ought all to be restless for improvement. If other people know more than we do, or can do better than we, let us find it out. Until the photographic art is perfected let us strive for improvement. No photographer has exhausted his capacity,—the pictures which are to bear off the prizes next year are not yet made; the best marksman always aim at the bull's-eye, although he miss it half the time.—*American Journal of Photography.*

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 18th September, 1861.

One of the most interesting features of the present Industrial Exhibition at Marseilles is a series of 200 photographs of engravings from the works of Rubens. These have been collected into five volumes, bound with descriptive text, and published by M. Muquardt of Brussels, at 200 francs the volume. The first volume consists of subjects taken from the Bible, the second contains "Assumptions," "Ascensions" of the Saints, &c. Unfortunately, the progress of this important work has been stopped by the illness of the publisher, who has become insane. These photographs are among the best specimens I have seen of copied engravings, and indeed might under some circumstances be taken for them. "The Brazen Serpent" and an "Elevation of the Cross," are remarkably fine. As the original engravings are very scarce and dear, this publication may be regarded as a boon to art amateurs.

Some photographs from the original pictures of Rubens representing landscapes with men and various animals are not so successful. In this case the difficulties to be overcome were greater, the painter has made use of colours which are not translated in black and white in the camera as in the engraving. However, with all their shortcomings and defects, they possess a certain kind of interest which will reward the photographers for their trouble.

The production of new colouring materials is certainly one of the most remarkable events in the chemical science of the present day; and in this particular coal tar has played the most prominent and important part. M. Ruhlmann has just made public his discovery of a new blue colour obtained from cotton-seed oil. This colour is chemically pure; burned on a slip of platinum it leaves no ashes; every effort to obtain it in a crystalline state has failed. At a temperature of 68° Fah. it is soluble in alcohol of 90° only in the proportion of 1·30 per 100, and in 12 per 100 in pure ether; by the aid of heat it is dissolved more freely, to be deposited in a granulated state upon cooling.

In cold alkaline solutions it is insoluble, but by a long ebullition a small quantity is dissolved, which slightly colours the liquid green.

The new colour is slightly soluble in chloroform, and in sulphide of carbon. In contact with concentrated sulphuric acid, it is dissolved and assumes a purple colour. Upon adding water to this solution the blue colour reappears, and is completely precipitated. Boiling phosphoric, hydrochloric, and acetic acids have no effect upon it.

The reducing agents generally, such as nascent hydrogen, sulphurous acid, the protoxides of iron and of tin, and arsenious acid, do not affect the splendour of the new colour, while the oxydizing agents, such as nitric acid, chromic acid, perchloride of iron, chlorine, bromine, iodine, destroy it immediately upon contact.

The new colour is obtained by keeping the cotton-oil at a temperature of 212° F., for five or six hours, with 3 to 4 per 100 of concentrated sulphuric acid. This contact of oil and acid must be prolonged until the green colour of the oil is changed into a deep blue colour. The blue substance thus obtained contains 48 per 100 of fatty acid; it retains a little free sulphuric acid and some sulphate of soda or sulphate of lime. Repeated washings with warm water separate these latter products, and this separation is still more complete when after washing in water the blue substance is dissolved in alcohol, and afterwards precipitated by water, which retains only a trace of it, but which separates the acid and the sulphates which escaped the washing. In order to separate the fatty body the blue substance must be washed many times successively in naptha, which also dissolves a little of the blue colour so long as any of the fatty body remains in the mixture, but which dissolves only a trace of it when these washings have been several times repeated. Analysis shows its composition to be $C_{34}\ H_{24}\ O_8 =$

$$\begin{array}{l} C\ 69{\cdot}87 \\ H\ \ 8{\cdot}22 \\ O\ 21{\cdot}91 \\ \hline 100{\cdot}00 \end{array}$$

It is difficult to avoid regarding this substance as a new definite organic compound, which combines with nitric acid, chlorine, iodine, and bromine.

The best mode of practically applying this new pigment remain to be discovered; but when we consider that it resists the action of the most powerful acids, viz., concentrated phosphoric and sulphuric acids, like indigo, and of other agents which destroy the colour of indigo, such as boiling perchloride of tin, and muriatic acid, it may be expected that indigo and prussian blue have encountered a formidable rival in this new blue.

Apparatus.

CAMERA FOR FOUR PORTRAITS.

Sir,—I send you particulars of my invention for taking four or more photographs on one plate with one lens. The grand difference between this method and that of other persons who have attempted the same thing, is that while they try to effect their object by some arrangement of the dark slide, or by a modification of the back part of the camera, my plan attains the desired end by means of a circular disc carrying the lens, and working inside the front of the camera; for instance, the camera is divided into four parts by partitions running lengthwise. The lens, in a circular front, which revolves on a pivot in its centre, is placed opposite the lowest or first division. The portrait is taken, the lens is then moved up to the division No. 2, or the one immediately over the first. The next picture is impressed, and so on for the remaining half of the excited plate. There is only one focussing and that is at the commencement. The proper place for the lens to occupy in its course is marked on the front, so that the four pictures are photographed rapidly with merely taking picture the first, putting on the lap, shifting the lens to the next place, exposing and repeating these simple operations through the series until the last one is taken. I shall be happy to furnish any further information about the method should it prove desirable.—I remain sir, yours respectfully, JAMES J. MAGINN.

Manchester, September 11, 1861.

[If we are not mistaken, Mr. Francis constructs a repeating camera on a somewhat similar principle.—ED.]

Photographic Notes and Queries.

ERECTING FOCUSSING GLASS.

DEAR SIR,—If you or any of your numerous readers would, in your answers to correspondents, inform me what number of lenses, with their respective form and foci is required, and what their respective distances apart, in the construction of an erecting focussing glass, you would confer a very great favour on, yours truly, &c., ENQUIRER.

Wigton, September 10.

[We cannot recommend you to attempt the manufacture of an erecting focussing glass, as it must necessarily be a cumbersome and clumsy instrument, and of little service when made; a very little practice renders the eye familiar with the image in its inverted position on the ground glass. As you do not state what magnifying power you require, we can only give you the formula for an ordinary erecting eye-piece, by modifying which you may obtain one of the power you wish. In one of the best forms of the ordinary erecting eye-piece which we know, there are four plano-convex glasses, the first and second of which—that is those next the eye—should have their plano sides towards the eye: the third and fourth their convex sides towards the eye. The radii of the glasses, as follows: the first ·65; the second 1·1; the third ·95; the fourth ·9. The separation between the glasses as follows: between the first and second 2; between the second and third 2·5; between the third and fourth 2·5. Between the first and second a stop must be placed in the focus of the first, of such diameter as will give the required field; and between the third and fourth a stop of about ·25 placed in the focus of the fourth. These radii and distances taken in inches or parts of an inch, will give an erecting eye-piece the equivalent focus of which would be ·7, enlarging about 12 times. As for focussing purposes a power of 4 times is the highest that should be used, you will readily see on multiplying the above figures by three what a cumbersome instrument must result.—ED.]

Talk in the Studio.

NOVEL APPLICATION OF PHOTOGRAPHY.—We were somewhat amused in Manchester to observe on the placards in the lobby of the Exchange, that the index, or hand, pointing the way to the Photographic Exhibition, was the photographic image of a hand taken from life. One of Manchester's most able amateurs and scientific men, we were informed, had "lent a hand" for the occasion.

THE INTERNATIONAL EXHIBITION.—Her Majesty's Commissioners are sending out forms to all known photographers, which they are invited to fill up, stating the space, &c., they will require for exhibiting photographs at the forthcoming Exhibition. All applications must be made before the 30th instant, which is the last day for receiving applications.

PHOTOGRAPHY AND THE WAR.—The *American Journal of Photography* says:—Photography seems not to suffer quite so much from the war as most other avocations. Photographers in the neighbourhood of military recruiting are even doing better than usual. The photograph has become almost an article of necessity. As long as there is a giving in marriage, or the population is increased, the photographer must be in demand. Photography is a habit with some people; it is the mirror in which the belle discovers how she looked on yesterday.

THE CAUSE OF THE PANIC AT BULL'S RUN.—One of our American contemporaries, *Humphrey's Journal*, states that the panic in the Federal army, was caused by the sight of a photographer's camera! "Brady has shown more pluck than many of the officers and soldiers who were in the fight. He went—not exactly like the 'Sixty-ninth,' stripped to the pants—but with his sleeves tucked up and his big camera directed upon every point of interest on the field. Some pretend, indeed, that it was this mysterious and formidable looking instrument that produced the panic! The runaways, it is said, mistook it for the great steam gun discharging 500 balls a minute, and incontinently took to their heels when they got within its focus! However this may be, it is certain that they did not get away from Brady as easily as they did from the enemy. He has fixed the cowards beyond the possibility of a doubt. Foremost amongst them the observer will perhaps notice the well-known correspondent of the London *Times*; the man who was celebrated for writing graphic letters when there was nobody by to contradict him, but who has proved, by his correspondence from this country, that but little confidence can be placed in his accounts. See him as he flies for dear life, with his notes sticking out of his pockets, spurring his wretched-looking steed, his hat gone, and himself the picture of abject despair." Mr. Russell's letters, it would seem, have been too true and "graphic" to be palatable to our transatlantic cousins, and he is, of course, therefore, a falsifier and a poltroon!

To Correspondents.

E. S. H.—If you send us one of your prints we can possibly tell you how to remedy the defect in your lighting. But without seeing the nature of the fault it is difficult to advise. You will find some hints on a substitute for a glass house at p. 296, vol. i, of the PHOTOGRAPHIC NEWS.

A. D. O.—The defect to which you refer, we presume, is the slight amount of tint or discolouration which pervades all the lights of the picture. It would scarcely be considered a defect by some, although it doubtless slightly deteriorates the brilliancy of the print. If white light reaches the paper in any of the operations, that would cause the tint. If you are quite sure you are sufficiently careful in this respect, probably your silver bath is alkaline. A slightly acid reaction is desirable in the printing bath, especially in warm weather, as that will prevent a tendency to spontaneous decomposition of the free nitrate. You may add either acetic acid or nitric. We prefer the latter.

J. C.—There is no reason whatever why the albumenizing and drying of your plates should not be conducted in daylight. The reason why the instructions given for carefully removing dust from the dark-room, and operating there, is, we presume, because that room will be most sacred from intruders, causing draughts, &c. Use any room most convenient to you, only be careful to exclude dust. The wrinkling of the film may be caused by imperfectly cleaned plates, but most probably by the layer or albumen being too thick, and not of a uniform thickness. If the layer be thicker to one end, that end will be most likely to wrinkle. Take care to have the plate perfectly dry before sensitizing.

G. A. E.—We believe the firm to which you refer, Messrs. Hope and Co., is no longer in existence.

L. A. M.—A slight addition of acid to your bath will probably remove the white streaks. A little tincture of iodine added to the collodion will sometimes answer the same purpose. We are not familiar with the working of Jamin's combinations, but so far as we remember, the arrangement for using them as portrait lenses of long focus—in your case for whole plates—consists in removing the back lens entirely, and reversing the tube in the flange so that the front lens becomes the back lens, and the middle lens the front one. The hood of course must be first removed, and then replaced when the lenses are in their new position.

ROBERT DOUGLAS.—We do not remember receiving your letter: will you be so good as to write again, stating its purport.

J. M.—It is undesirable to allow your prints to soak in water very long before toning. Two or three changes of water, and five minutes in each, will remove the free nitrate sufficiently. Slow toning is best; rapid toning is conducive to mealiness.

T. G. L.—The proper place for the stops in a portrait combination ought to be fixed by the optician. The rule is as nearly as possible in relation to the foci of the lenses. Thus: if the focus of the front lens be 6 inches, and that of the back 12 inches, and the distance between the lenses 3 inches, the position of the stop would be 1 inch behind the front lens. You may also ascertain the best place by trying several positions until you find one which has the greatest freedom from distortion.

M. M.—We do not like a wide stereoscopic angle. The exaggerated relief it gives is not truth. We use a binocular camera ourselves. Of course, the prints must be transposed in mounting.

F. G. F.—We use methylated spirits in the developing solution, and find no disadvantage of any kind. It is of course much cheaper.

NIL STANNI.—The purport of your remarks is, perhaps, right; but your letter is not sufficiently courteous in style for publication. We shall probably have something to say on the subject.

EXCELSIOR.—The extent of field covered by a lens does not depend upon its diameter, but upon its length of focus. In a common landscape lens the field covered is generally about two-thirds of the focus. A lens of 20 inches or 21 inches focus may therefore easily enough cover 14 by 12. We can of course form no opinion of this individual lens, but there is no reason why it should not be a good one, and the price is certainly moderate. In order to obtain perfect definition to the edges of the plate you will have to use a small stop. 2. The discolouration of your iron developer is not necessarily a defect. It sometimes works better when it has become somewhat brown. Don't throw it away whilst it does its work.

OUR WEEKLY CONTENTS.—We beg to inform several subscribers that it is not our intention to omit the weekly index. The outside sheet goes to press before the remainder of the number, and the contents were omitted once or twice when we were from home, because it was uncertain, at the time the cover went to press, what articles would be inserted.

MINERAL CARBON, JOHN SYMONDS, THOMAS ANNAN, WILLIAM BIRCHAM, T. S. SWATRIDGE, H. COOPER, D. L. I., and some other correspondents in our next.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 160.—*September* 27, 1861.

THE FORTHCOMING INTERNATIONAL EXHIBITION.

There remain three days after the date of the present number, for photographers to make application for space in which to exhibit their works in the International Exhibition of 1862. On the first of October the opportunity for making such application will have passed. Many photographers have already sent in their applications for space; but some, we fear, either from procrastination, or from the misunderstanding between Her Majesty's Commissioners and the Photographic Society, have as yet failed to make any application.

Whatever may be cause of such neglect, whether it arise from intention or thoughtlessness, we earnestly conjure all who can produce pictures which will worthily illustrate the art, to lay aside minor considerations, and at once take the proper steps for securing to their works a place in this exhibition of the whole world's industry and art. There is a season for all things: there are occasions when it is necessary to a man's self-respect that he should stand upon his dignity; but the issues here involved are altogether too important to be sacrificed to any petty considerations of *amour propre.* This is the first occasion on which the photographers of the world at large, have had an opportunity of joining forces, to illustrate the gigantic strides the young art has made towards perfection during its brief existence. In the year 1851 the scope of photography was very limited, and the art, as now practised, was scarcely known. It has now attained an importance then undreamt of, and it would be ten thousand pities to allow any small consideration to mar the completeness of our representation in this great international undertaking.

We have referred to the circumstances which have arisen to damp the enthusiasm of photographers as a misunderstanding; and we use the word advisedly. At the first announcement of the intended classification we were disappointed and outraged at the allocation in which we found photography, and without delay called the attention of the Commissioners to what we regarded as their mistake in classification. Subsequently, however, we find the Commissioners assuring the council of the Photographic Society of their desire to do all honour to photography, intimating their intention of giving a separate apartment for the display of the photography of the world, and asking the Society to appoint a committee to co-operate with them. We have already repeatedly said that we believe the Society would best have served the interests of the art and its votaries by appointing a committee, who might, by judicious management, have obtained all that photographers could hope for. The desire on the part of the Commissioners to have a committee appointed by the Society was the best guarantee of their wish, as far as possible, to meet the demands of photographers. That they should immediately and unhesitatingly alter their arrangements, and suffer terms to be dictated, was more than could be hoped; whilst the offer of a distinct apartment was, with one exception, the very best thing that could be done for the art. The only other concession which we should like to have seen made was the effecting of some change in the nominal classification or cataloguing, so as to remove photography from what was regarded as its derogatory associations. Unfortunately the Society felt concerned to maintain an uncompromising position, demanding all concession from the Commissioners before they could consent to co-operate in any way.

The end of all this is, that the energy which should have been employed in actively preparing during the summer, specimens for exhibiting next year, has been dissipated by this misunderstanding. Uncertain of what was to be the issue, photographers have remained so long in a state of suspense that the interest in the matter has waned, and some from indifference, some from forgetfulness, and some from disgust, have failed to make any application which may enable them to take part in the exhibition. This state of things is, we repeat, much to be regretted; for the sake of the art, and for the sake of England's credit in connection with it, English photographers should do their best to secure a worthy representation.

As our readers are aware, the French society declined to recommend French photographers to abstain from exhibiting. We have reason to believe that the contributions of French and other continental photographers will be large and of high quality. The present exhibition of photographs in France is one of the most important, both in extent and excellence, that has been known; the number of specimens amounting to some thousands, and the majority exhibiting the highest ability. Some thousands of photographs are also now collected in the exhibition at Florence. Surely then if England invites the world to a competitive exhibition of its productions, English photographers will not willingly be distanced or surpassed in such a competition, or at least not without an effort to maintain supremacy.

All minor considerations should be now laid aside. Photographers have made their protest. If their works be pronounced as worthy of the niche in the Temple of the Fine Arts which they claim for it, no mistaken arrangement in classifying will prevent its taking its proper position in the minds of the educated public. Let us admit for the present that the art does occupy a novel position; it is young, and has yet to win its spurs. We have no doubt about its claim to a fine art position; but if others doubt it, let us prove its claims practically rather than verbally. Let us produce works of art that will not admit of cavil. Engraving had to fight for its position, and has but recently received formal recognition of its claims. Photography also will have to prove its claims; but a representation at the present exhibition of overwhelming excellence, will be one of the most important steps that can be taken to that end, and no matter how catalogued, let us be content to await the world's verdict.

There is just time, for those who have neglected hitherto, to make their applications for space, which must be sent in before the termination of this month. Forms of application may be procured from the office of the Commissioners, 454, West Strand. For the assistance of those who may not have time or opportunity for securing these, we subjoin the form in which applications must be made, and once more conjure our readers to exert themselves for the honour of the art.

INTERNATIONAL EXHIBITION, 1862.

DEMAND FOR SPACE.

	(To be written very clearly.)
1. Name and Christian of Applicant (or Name of Firm) - -	
2. Nature of business carried on -	
3. Address { No. of Street or Square, and Name of Town - -	
4. Nature of Articles to be exhibited	
5. Class* in which they are to be exhibited - - - - -	No.

	Floor Space.		Hanging, or Wall Space.	
6. Probable space that will be required for Articles, or for Case in which they will be shown -	Length	feet.	Height	feet.
	Breadth	feet.	Width	feet.
	Height	feet.		

"UNTOUCHED" PHOTOGRAPHS.

What is an untouched photograph? This is a question recently asked of us by a correspondent, referring to some comments we made on a photograph in the Manchester Exhibition. The picture was a very fine one of "Loch Ranza," by Mr. Annan of Glasgow: it was marked "untouched;" but we observed that it had some suspicious looking clouds. Mr. Annan informs us that it was printed from two negatives; but that neither the negatives nor the print was touched. Mr. Annan adds:—

"I have often seen, and believe it is the universal custom to stop out the skies, and tone them down in the print. That is double printing, and yet I never saw them challenged as "touched" pictures, and I thought I had a better right to call mine untouched, than those who paint out their skies in the negatives.

"My method of printing is this; the greater part of my negatives are taken by the wet collodion process, and generally my skies are dense enough to print pure, and the tannin negatives likewise, or when they are not I protect them while printing by some simple appliances, always taking care that the horizon is never interfered with, and then I print in my clouds which are taken from *nature*. And notwithstanding all that has been said against this way of getting clouds, I believe it is the only way at present of getting a natural daylight-look about a photograph."

He further adds, that even the best photographic landscapes, with natural clouds taken at the same time, have an effect more like moonlight, than the broad light of day.

We readily admit part of this allegation. Many photographs which have had a sufficiently short exposure to secure natural clouds, have a sombre, evening, or moonlight effect. But this is by no means universally true. We have seen many, and we have some, photographs with fine clouds and atmosphere, but which are yet suffused with sunlight. These of course are restricted to certain subjects. Where much green foliage is present, we admit it is next to an impossibility to render all its details, and secure at the same time the perfect forms of clouds. This is a subject into which, however, we cannot here enter at large.

We have now to answer the question—What is an untouched photograph? We think it should be taken to mean a print as it is produced from the negative, without "dodging" of any kind whatever. If literal verbal accuracy only be regarded, the word might admit of much quibbling. What is "touching?" In its technical sense the term is applied to the process of improving the print by means of the artist's pencil. But why should the operation be confined to pencil and pigment? The application of the pencil of light, if it produce a similar result, is surely still touching. And if this be admitted, where shall we draw the line? The term "untouched" is unquestionably meant, in its absolute sense, to describe a perfect print from a perfect negative, needing no aid from the hand of the artist. The French meet the case very stringently: in their present exhibition there are many specimens marked as without retouching in either negative or positive. Some will exclaim, surely, a picture is not to be disqualified from a position amongst "untouched photographs" by having a few spots "touched" out. It is a difficult point to decide: if a spot may be stopped out, why not a sky? and if a whole sky, why not part only, so as to produce clouds?

Perhaps we may meet this view of the case by asserting that, except as a kind of photographic *tour de force*, we do not attach an overwhelming value to the idea of being untouched. We delight to see perfect photography. A negative without blemish of any kind whatever, free from spot, stain, or fog, and full of exquisite gradation, affords us a technical pleasure, altogether apart from the prints it will produce. But when we come to the question of results, we would rather see an artistic picture than technically perfect photography. We would prefer to see an awkward figure masked out, a harsh outline subdued and toned down, however perfectly rendered it may have been in the negative. We do not object to the indication of clouds in the negative, if it be done well; nor to the printing from two negatives, if the harmonious conditions necessary to produce natural effects be observed. As we have before remarked, in these matters success is the test of legitimacy.

Some time ago, when Mr. Samuel Fry introduced this method of double printing to the South London Society, it met with much opposition from some good photographers, who regarded it as a step in the wrong direction, destructive of the truth of photography, and as tending to raise the mechanical art of neatly combining several negatives to make one picture, rather than the higher art of securing perfect results without such contrivances. Whilst heartily sympathising with the intention implied in the condemnation of this practice, we must admit there are cases where the results are good and the practice commendable. We cannot decry the application of artistic taste and skill in the process of printing. The more perfect the negative the less of this skill it will require in producing prints; but we think that in printing from defective negatives, the application of the taste and judgment of the artist, in concealing defects or adding beauties, is both legitimate and desirable. It is not the principle, but failure in applying it, which is to be condemned. The legitimacy of some such practice is universally admitted; the only doubt seems to be where to draw the line. Vignetting is the simplest form in which the principle can be applied; then follows masking some parts of the negative, then the tinting of skies, then the painting of clouds on to the negative, and then double printing. All these are based on one principle, the desire to produce a finer print than the negative in its simplicity and entirety will yield The more complex the method, and the more ambitious the results aimed at, the greater the knowledge and skill necessary to secure success. As a general principle the simplest methods, and the most unpretending the results, are those most certain to please, or at least pass unchallenged.

All this brings us once more to the consideration we lose no opportunity of urging upon photographers—the im

* Photography is Class 14, Section II.

portance of education in art. With a mind and eye cultivated to the careful observation of natural and artistic truth, the photographer could never be guilty of gross blunders in this respect. And whether a picture have been produced at once by the most perfect photography, or whether it required the application of all the multiplied appliances which could be brought to bear upon its modification, it will not be tolerated without it possess, in addition to whatever other qualities, something of harmony, keeping, and truth.

PHOTOGRAPHIC CHEMICALS:

Their Manufacture, Adulterations, and Analysis.

Nitric Acid—continued.—The ordinary impurities likely to be present in commercial nitric acid require a little attention. They are *hyponitric acid, chlorine, sulphuric acid, iodine, potash and soda salts, sesquioxide of iron*, and other fixed substances.

Hyponitric acid is a very frequent impurity, but it is one the presence of which is not of much consequence to the photographer. It is difficult to remove, and even if after considerable pains an acid has been obtained free from it, it soon forms again. as, under the influence of light or heat strong nitric acid spontaneously splits up into hyponitric acid and oxygen. It is, therefore, not worth the photographer's while to attempt its removal. Its presence in nitric acid is the reason why this acid when diluted with two or three times its volume of water precipitates sulphur from an aqueous solution of hydrosulphuric acid, and separates iodine from iodide of potassium; neither of which the pure acid would accomplish.

Chlorine is a much more serious impurity, and one which should not on any account be allowed to be present. It is easily detected by diluting the acid with four or five times its bulk of water, and adding nitrate of silver. A white precipitate shows the presence of chlorine. The concentrated acid may be freed from this impurity by heat, the chlorine together with the hyponitric acid and a portion of nitric acid distilling over first. Some writers recommend a process of precipitating the chlorine by nitrate of silver from the dilute acid, decanting from the insoluble chloride of silver and distilling from the excess of nitrate of silver. We do not, however, recommend this, as it is very troublesome, and not a bit more effectual than the former method of heat. The process of distillation over metallic silver, recommended by Bescherer, is not accurate, as some of the chlorine may still pass over with the nitric acid. The acid cannot be purified from chlorine by means of oxide of lead, because the chloride of lead dissolves in the nitric acid, and is again decomposed on the application of heat.

Sulphuric acid may be either an accidental impurity or an intentional adulteration. In the latter case it is added for the purpose of raising the specific gravity of a weak to that of a strong acid, and consequently making it appear of more value than it otherwise would be. As an accidental impurity it may be present from the neck of the retort becoming soiled when the acid is poured down it; from the spirting of the mixture; or from using too large a quantity of oil of vitriol, and heating too strongly. It may be readily detected by diluting with four or five times its volume of water, and adding nitrate of baryta. A white precipitate indicates the presence of sulphuric acid. This impurity is readily removed by redistilling from a small quantity of nitre, or by precipitating the previously-diluted acid with pure nitrate of baryta, allowing the precipitate to settle, decanting and distilling the clear liquid.

Iodine is not an uncommon impurity in nitric acid, owing to Chili saltpetre (nitrate of soda) containing this body. It may be detected by neutralizing with potash, adding a little starch paste, and then adding oil of vitriol slowly, drop by drop. The smallest trace of iodine causes the liquid to assume a blue colour. The iodine may be removed by careful distillation. The nitric acid comes over first, and leaves the iodine till towards the end of the operation.

Potash and *soda salts, sexqui-oxide of iron*, and other *fixed substances*, are detected by evaporating a little of the acid to dryness at a gentle heat. A solid residue will show the presence of some such impurity. It can be removed by distillation.

Sulphuric Acid.—This is one of the most important chemical agents known, both on account of its intrinsic valuable properties, and owing to the numerous other substances, for the manufacture of which it is necessary. Thus without sulphuric acid the photographer would have no ether, guncotton, nitric acid, iodide of potassium, hyposulphite of soda, nitrate of silver, sulphate of iron, and many other less important chemicals, or at all events the difficulties in their manufacture would be so greatly increased as to amount to almost a prohibition of their use; whilst the commercial value of this acid is such that its manufacture is one of national importance, the fluctuations in its price affecting chemical and other works in nearly every town in the kingdom.

The ordinary form in which sulphuric acid is met with is in that of *oil of vitriol*, which is a very heavy, oily-looking, highly corrosive liquid, consisting of one part of the anhydrous acid, with one part of water. It is only prepared on the large scale by burning sulphur mixed with one-eighth of its weight of nitre in a spacious chamber made of lead, filled with air and aqueous vapour, and having its floor covered with water. The nitrous acid obtained from the nitre, acts as a carrier of oxygen, taking it from the air, and giving it up again to the sulphurous, which is thereby converted into sulphuric acid; the reproduced nitrous acid being ready to carry a fresh portion of oxygen to another portion of sulphurous acid. The sulphuric acid which is thus formed dissolves in the water, which is at the close of the operation drawn off and concentrated by evaporation, till it becomes of a density of 1·78, when it is further purified by distillation. Formerly platinum retorts were used for this purpose, and as these were required to be very large and of a sufficient thickness to stand wear and tear of use, their expense was an important item in a sulphuric acid works, a large still costing some thousands of pounds. Lately, however, glass retorts are coming into use again, the manufacture of these having been greatly improved, so that they are now supplied of a larger size and superior quality. The above is a brief outline of the process of manufacturing English oil of vitriol. On the Continent it is made in a different way. Green vitriol, which has been freed from its water of crystallization, and converted into sulphate of the peroxide of iron by heating it in the air, is placed in earthen retorts heated in a reverberatory furnace. The acid is received in earthen receivers, into which a little water, or what is preferable, common oil of vitriol, is placed. In this way a light brown, viscid, oily liquid is obtained of 1·896 specific gravity, fuming in the air, and evolving thick white vapours of anhydrous sulphuric acid when heated. This quality is called *fuming*, or *Nordhausen* oil of vitriol.

The English oil of vitriol, which is the only quality which the photographer is likely ever to require, is a colourless, transparent, oily liquid, which is inodorous, and non-volatile at ordinary temperatures. Its specific gravity is 1·848, it boils at about 300°, and passes off unaltered, forming a thick white cloud when in contact with the air. It corrodes organic matter strongly, being coloured brown by them, a drop of it falling on wood or the clothes, charring and destroying them like a red hot iron, in a few minutes. It has a most powerful affinity for water, one part of oil of vitriol placed in an atmosphere saturated with aqueous vapour, absorbing 15 times its weight of water. Its combination with water is attended with great heat; 4 parts of oil of vitriol being mixed with 1 part of water raising the temperature from the freezing to the boiling point of water. Strange to say, however, if oil of vitriol be mixed with a little more than its own weight of snow, intense cold is produced. When the diluted acid is boiled, water goes off and oil of vitriol is left, which upon increase of temperature distils unchanged.

The characteristic test for sulphuric acid, either alone or in combination with bases, is its forming a compound with baryta, which is perfectly insoluble in water and dilute acids. If a very dilute solution of sulphuric acid be mixed with chloride of barium, a white precipitate is formed which is insoluble in nitric or hydrochloric acid. No other re-agent acts in a similar way. The delicacy of this test is such that a solution containing 1 part of sulphuric acid in 100,000 of water, produces a turbidity when mixed with a baryta salt, and even in 200,000 parts of water a cloudiness is produced after the lapse of 15 or 20 minutes.

PRINTING AND TONING.

BY J. C. LEAKE, JUN.

The importance of this branch of the photographers' art cannot be over estimated. It is the process for which all the other processes are made. The public care not how we produce our negatives, but they do care a great deal about our printing. Reasonably they ask are they permanent, and reasonably they point the defects so painfully apparent in so many photographic prints. Thus it becomes of vital importance to produce permanent and beautiful prints, as on this the future success, perhaps, I might say the very existence of photography depends. These considerations have led me to lay before your readers a few remarks on some of the conditions required in order to produce the best results.

To begin at the beginning, it has been often said that to produce a brilliant print by the alkaline toning process a much more intense negative is required than is necessary for the old sulphur toning. This is a mistake; any negative that will print a *good* proof by the old method, will, at least, do as much by the new; and experience leads me to the belief that most negatives are too intense; much of the delicacy and beauty being destroyed by the long-continued action of pyrogallic acid and silver, which completely obliterates the more delicate details and destroys the gradation.

It is not intensity, as it is generally understood, that will give brilliance, but a complete system of gradation, a perfect series of tones starting from bare glass in the deepest shadows. And to this must be added a good printing process; and some skill and judgment in the treatment of each particular negative as its peculiarities may require.

We are practically restricted to the use of two kinds of paper, *Rive* and *Saxe*, the English papers are too coarse and absorbent. Of these the *Rive* is the best, on account of its superior hardness and fineness of surface. The *Saxe* is, perhaps, more free from blemish, and the black tones are more easily produced on it; it is also free from the plague of blisters. For small pictures the *Rive* is best, while for large ones *Saxe* may possess some advantages. Of albumenizing nothing need be said, as most persons procure their paper ready for use. I must, however, remark that many of the defects attributed to bad albumenizing are really owing to defective paper.

The next process, that of sensitizing, is, perhaps, the most important of all. A little neglect here and all the care bestowed upon the former and subsequent operations will be lost. It is a vital point to keep up the strength of the silver solution. Unless this be done, no depth of tone can be obtained, the prints will lack brilliance, and will be grey and mealy. The strength usually recommended, sixty grains to the ounce is often not enough for the amount of salt in the albumen; seventy is a safe quantity for all ordinary purposes, and to this standard it should at least be kept up.

So long as the paper keeps white for twelve hours no addition of acid need be made to the solution; but a tendency to yellowness in or to the removal of the albumen from the paper will be best removed by a few drops of acetic acid. A sample of paper, which removed all the colour from the sensitizing bath, was recently brought under my notice. To prevent any difficulty from this cause now, I am informed not unfrequent, the bath should be kept perfectly colourless by means of kaolin.

Three minutes will be found quite long enough to allow the paper to remain on the bath. It is better not to let the solution soak into the paper, or a loss of brilliancy will result.

The little instrument used in the kitchen to time the boiling of eggs, will be found useful for timing this part of the process. The paper is better if dried before a fire; and it should be used at all events before twenty-four hours, and the sooner the better.

After removal from the pressure frames the prints should be well washed to remove the free nitrate from the surface; it is as well to perform this operation quickly, or the paper will become saturated with the nitrate solution which will interfere with the toning process.

The toning baths most usually recommended are three, as follows:—

No. 1.—Carbonate of soda	...	5 grains
Chloride of gold ...	...	1 grain
Water	...	10 ounces.

My impression is that this is the worst of the series here to be mentioned. It has to be used warm, it is not so economical as either of the others we shall name, and as it will not keep and cannot be used a second time it is very inconvenient; it, moreover, reduces the print considerably, rendering necessary considerable over-printing.

The next bath, known as Maxwell Lytes, we will call—

No. 2.—Phosphate of soda	...	18 grains
Chloride of gold ...	...	1 grain
Water	...	4 ounces.

This is decidedly the better bath of the two, as it will keep a day or two after mixing, and it does not reduce the print nearly so much as that first mentioned. The proofs are a nice purple tone with velvety shadows.

The acetate of soda bath, known as the Abbe Laborde's.* is, however, superior to both of these. The formula I use stands thus:—

No. 3.—Acetate of soda ...	...	½ ounce
Chloride of gold ...	...	4 grains
Water	...	1 pint.

This bath must be mixed twenty-four hours before use. It has, in my hands, proved very successful, the prints are of a rich warm tone; and it is difficult to obtain anything like coldness or mealiness if ordinary care be taken. It may be used over and over again till all the gold be abstracted. The best method of proceeding is as follows:—Mix, say a pint, and use it till it begins to work slowly; then mix a second pint, and from time to time add as much fresh solution as may be required to make it work comfortably. This bath must always be used cold; it tones in about ten minutes, and the over-printing need be very slight, as the depth is but little altered.

This is my favourite method of toning, and it approaches nearly my ideal of a toning process in the following particulars:—First, the solution may be kept without deterioration; second, it may be used cold; and, thirdly, it does not reduce the print; all three being good points, the last named in particular.

There are two more toning baths which have been used by me with some success, these are that with chloride of lime (Legray's), and one with carbonate of ammonia. The formula for the first is as follows:—

Chloride of lime	... ...	5 grains
Chloride of gold	... ...	5 grains
Water	... ...	1 pint.

In this bath the prints are bleached a good deal, but not more than in the carbonate of soda bath before-mentioned, and the tones of the finished pictures are rather colder than

* The credit of the first suggestion as to the use of acetate of soda in conjunction with gold in toning, is due to Mr. Hannaford.—Ed.

where the acetate or phosphate of soda is used. For the carbonate of ammonia bath mix—

Carbonate of ammonia	...	10 grains
Chloride of gold ...	...	5 grains
Water	...	1 pint.

Both of these solutions to be used cold; the latter will keep two or three days, and both must be mixed a few hours before use.

The process with carbonate of ammonia seems a promising one, and the prints have somewhat the effect of those toned in the old toning bath of hypo and gold.

After toning in any of these solutions, the proofs should be *well washed* before fixing. This operation should be quickly and carefully performed. A solution of hyposulphite of soda, six ounces to a pint of water being poured into a deep dish, the prints should be carefully immersed, one at a time, kept constantly moving, and be well watched. As soon as the fixation is completed, which may be ascertained by looking through the picture, it should be at once removed and well washed, back and front, each print separately, before being placed in the dish or trough in which the prints are left to wash and soak in common.

BEATTY'S PATENT HELIOGRAPHIC PRINTING.

For the Production of Photographic Representations in Printers' Ink.—[*Communicated.*]

The object of this invention is to extend the application of photography, by substituting for the salts of silver (used in the ordinary printing of a photograph), an imperishable and cheap material, "printers' ink," and printing the impression at the printing press now in use; thereby rapidity of production, and consequently, cheapness will be the result.

By photography the most elaborate and minute design can be copied of any desired dimensions, and by the heliographic printing the impressions of those designs can be multiplied, and at the same time preserve the delicate pencil of the sunbeam as the graphic agent.

If then the photograph can be thus printed in printers' ink with the same facility as a drawing on lithographic stone, made in the ordinary manner, or on a metal block, for the purpose of printing by the ordinary letter-press, without the preliminary cost of engraving or drawing, there can be no reason why the most beautiful designs and drawings should not be sold at a price but little above the cost of the paper on which they are printed.

Therefore, the advantages to be derived by the introduction of this patented process may be considered with reference to the following:—

First.—It enables the photographer to give a perfectly faithful reproduction of the scene or object he may desire, without omitting the most minute detail, and if he wish, print on it a graduation of tints and colours with a certainty that these productions are not liable to fade.

Secondly.—The perfect reproduction of manuscript drawings by means of photography, and the transferring of them perfect on to lithographic stone for surface printing, or on metal blocks to print in combination with type, opens a new field to the artist, the architect, the surveyor, and the mechanical draughtsman, instead of having to rely upon the abilities of the lithographic artist, or wood engraver, to reproduce their design, and render to it the faithful character of the original, the patent heliographic printing process supersedes their labours, and offers peculiar and unique resources. Copies of architectural drawings, old or new maps, plans, and drawings of complex machinery, which would require much time and talent on the part of the draughtsman, would be available as soon as wanted, and the copy may also be enlarged or diminished from the scale of the original. As soon as the various professions are satisfied of the resources offered by this new art, it will become an indispensable appendage to every well-regulated publishing and lithographic establishment, as well as government offices.

Thirdly.—For the reproduction of valuable old and rare paintings and engravings of the olden masters. By heliographic printing processes we can produce a faithful transcript of the original, preserve the style and execution, by this means improve the taste, and form a correct judgment of their works; whilst the choicest of our modern works of art, the publishing price of which is beyond the reach of the general public, can be reproduced and published of any desired dimensions, placing the richest of our pictorial illustrations within the reach of all.

Fourthly.—Heliographic printing and copying by means of photography does not require the originals to be in printers' ink (recently printed), they copy alike from written documents or old printed matter and faithfully reproduce any number of impressions in fac-simile and in printers' ink. This art will be invaluable to the antiquary, to the librarian, to the curators of museums, to the legal profession, and to the Government for the preservation in fac-simile of valuable documents which now exist, and which are of so much value that the loss by risk or accident, such as fire, &c., &c., would be productive of great inconvenience and injury. Members of the legal profession are afforded a quick and economical means of having reproduced in fac-simile important documents, wills, &c., superior to any other mode of obtaining duplicates at present in use, and curators of museums will find in this art an endlesss resource for the reproduction of fac-similes of valuable literary curiosities for the benefit of the curious in such matters.

Fifthly.—The proprietors of extensive publishing, printing, and lithographic establishments will, by the introduction of the principle of the heliographic printing processes, be enabled to extend the resources of their business. As an example, the publisher of a work, by merely furnishing a copy of the book required to be republished, its pages can be copied by this process and made into surface printing blocks, including the engraved illustrations, if any, in a durable material—zinc, and can be of enlarged or reduced dimensions, to answer as a 12mo, 8vo, or 4to, saving the price of re-setting, reading, and the engraving of the illustrations. The advantages to the lithographer are so varied and important that it is needless to dwell upon them; suffice it to say that they are intimately interested in all that is stated, and also will be enabled to enrich their productions by copying by the process from the works of the best landscape, portrait, ornamental, and map, engravers, and are in possession of the means for the reproduction of photographs of external objects to illustrate books of all descriptions, as well as those gems of science and art, stereoscope pictures, printed in colours of a more permanent character than is now obtainable, and will be able to produce them at one-tenth the present cost.

Sixthly.—Map and chart publishers will, as a necessary consequence, avail themselves of a means whereby they can have at a cheap rate many sized maps from one original. And the Ordnance Survey of the kingdom will furnish materials for the production of detached maps of cities, and provincial towns, counties, parishes, townlands, estates, and forms for the purposes of the Landed Estates Court, and for the registry of deeds, or for sale at a moderate rate to the public.

And lastly.—Many advantages will be derived by the traveller, the philosopher, and the man of taste by this new art enabling them to reproduce their works for publication at a moderate cost. The botanist and the naturalist will be enabled to retain fac-similes of all objects whether flowers, leaves, trees, insects, or animals of any description that interests them most, These in general will not only contain a correct representation, but sufficient detail to afford a view of their distinctive character. In fact, every one who loves to study nature, either in her outward form by art, or to observe and trace her in the more obscure walks of science, must feel interested in so valuable a discovery, where, strictly speaking, art and science go hand in hand.

British Association for the Advancement of Science.

ABSTRACT OF THE REPORT OF THE KEW COMMITTEE.

The report of the Kew Committee opens with a statement of the extension of the system of photo-magnetic recording, and a reference to the various sets of instruments for carrying out these records verified during the year for different parts of the world. It then proceeds to the subject of photo-heliography, regarding which we make the following extracts, which will be interesting to our readers.

"At the last meeting at Oxford it was announced that the Kew heliograph was about to be transported to Spain for the purpose of photographing, if possible, the so-called red flames visible on the occasion of a total solar eclipse.

"It will be remembered that, at the suggestion of the Astronomer Royal, the Admiralty had placed at the disposal of the expedition of astronomers H. M. S. 'Himalaya,' and that the Government Grant Committee of the Royal Society had voted the sum of £150 for the purpose of defraying the expenses of transporting the Kew heliograph, with a staff of assistants, to Spain.

"Originally it was thought that a mere temporary tent, for developing the photographs, might have answered the purpose; but on maturing the scheme of operations, it became evident that a complete photographic observatory, with its dark developing room, cistern of water, sink, and shelves to hold the photographs, would be absolutely necessary to ensure success. The house, when completed, weighed 1,248lb., and was made up in eight cases. Altogether the packages, including house and apparatus, amounted in number to thirty, and weighed 34 cwt.

"Besides the heliograph, the apparatus comprised a small transit theodolite for determining the position of the meridian, and ascertaining local time, and the latitude and longitude of the station; and also a very fine three-inch achromatic telescope, by Dallmeyer, for the optical observation of the phenomena of the eclipse. Complete sets of chemicals were packed in duplicate in separate boxes, to guard against failure through a possible accident to one set of the chemicals. Collodion of different qualities was made sensitive in London, and some was taken not rendered sensitive, so as to secure as far as possible good results. Distilled water, weighing 139lb., had to be included; and engineers' and carpenters' tools, weighing 113lb., were taken.

"The total expenditure of this expedition amounted to £515, the balance of £362 over the amount granted by the Royal Society has been generously defrayed by Mr. De la Rue.

"Upwards of forty photographs were taken during the eclipse, and a little before and after it, two being taken during the totality, on which are depicted the luminous prominences with a precision impossible of attainment by hand drawings. The measurements which have been made of these prominences by Mr. De la Rue show incontrovertibly that they must belong to the sun, and that they are not produced by the deflection of the sun's light through the valleys of the moon. The same prominences, except those covered over during the moon's progress, correspond exactly when one negative is laid over the other; and by copying these by means of a camera, when so placed, a representation is obtained of the whole of the prominences visible during the eclipse in their true relative position. The photographs of the several phases of the eclipse have served to trace out the path of the moon's centre in reference to the sun's centre during the progress of the phenomenon. Now, Rivabellosa being north of the central line of the moon's shadow, the moon's centre did not pass exactly across the sun's centre; but was depressed a little below it, so that a little more of the prominences situated on the north (the upper) limb of the sun became visible than would have been the case exactly under the central line, while, on the other hand, a little of those on the southern limb was shut off. It has been proved by measuring the photographs, that the moon during the totality covered and uncovered the prominences to the extent of about 94″ of arc in the direction of her path, and that a prominence situated at a right angle to the path shifted its angular position with respect to the moon's centre by lagging behind 5° 55′. On both the photographs is recorded a prominence, not visible optically, showing that photography can render visible phenomena which without its aid would escape observation. Copies of the two totality pictures are being made to illustrate Mr. De la Rue's paper in the report of the 'Himalaya' expedition by the Astronomer Royal.

"Positive enlarged copies of the phases of the eclipse, nine inches in diameter, have also been made by means of the camera, and will be exhibited at the Manchester meeting.

"The work of the Kew Observatory is now so increased that it has become absolutely imperative to make some provision for working the heliograph in a way that will not interfere with the current work of that establishment; and Mr. De la Rue has been requested by his colleagues of the Kew Committee to take charge of the instrument at his observatory, where celestial photography is continuously carried on. This request Mr. De la Rue has kindly acceded to; and he will for a time undertake to record the sun spots at Cranford, as long as it is found not to interfere with his other observations. Mr. De la Rue has contrived, and had made by Messrs. Simms at his own expense, an instrument for measuring the photographs, which will much facilitate the reduction of the results. It consists of a fixed frame in which work two slides, moving at right angles to each other. Each is furnished with a vernier reading to 1-1000th of an inch. The top slide works on the lower slide, and carries a hollow axis 4½ inches diameter, on which rotates horizontally a divided circle reading to 10″, and this carries a second circle on the face of which are fixed four centring screws. An image intended to be measured is placed on the upper circle, and is centred by means of the adjusting screws; it is then adjusted by means of the upper circle in any required angular position with respect to the lower divided circle, so as to bring the cross lines of the photograph in position under a fixed microscope, supported on an arm from the fixed frame. By means of this instrument the sun pictures are measured so as to determine the diameter to 1-2000th of the radius; the angular position of any part of a sun spot and its distance from the centre are thus readily ascertained; or the differences of the right ascension and declination with respect to the centre are as easily read off to the same degree of accuracy.

"Mr. De la Rue has recently produced by his large telescope an image of a solar spot, and a portion of the sun's disc, far superior to anything before effected, and which leads to the hope that a new era is opened in heliography, and that the resources of this observatory might be further developed in that direction.

"At the last meeting of the Association the sum of £90 was voted for an additional photographer, and of this sum £50 has been received. The committee suggest that the balance of £40 be granted again at this meeting, as the full sum will be required during the ensuing year. A detailed account of this expenditure will be presented in the next annual report.

"Allusion was made in last report to an instrument constructed by Prof. William Thomson, of Glasgow, for determining photographically the electric state of the atmosphere. This instrument has been fitted up at Kew, where it has been in constant operation since the beginning of February last. It has been found to answer well in a photographic point of view, and Prof. Thomson has expressed himself much pleased with the results obtained."

WET COLLODION WITHOUT WATER.

BY COLEMAN SELLERS.

In a recent number of this Journal it is asked if I still use my glycerine process in the field—and if the flowing of the developed plate with glycerine before washing stops the development, &c. Having just returned from a short trip among the mountains, and having, as Oliver Wendell Holmes says, brought home with me cuticles stripped from the rocks and pine-trees, distant mountains, and beautiful clouds,—I feel better prepared to answer questions, and hoping that my experience may be of use to others I will in a few words show how I use the process.

Water is a good thing to have in the house, and a good thing to have in the field, but may be dispensed with photographically for a time thus:—Have in the dark tent, in addition to the usual chemicals, a bottle of glycerine diluted with one-third its bulk of water, also a bottle of silver solution twenty grains to the ounce, with one-quarter ounce of acetic acid to each ounce of solution. The addition of this acetic acid enables silver to be added to the developer already on the plate without staining. Having developed as usual, as far as the first application of iron will take it, examine its intensity and if it requires more silver add it from the solution above described, flowing it well over the plate, but not draining back into the bottle, then pour on more developer. This can be repeated without washing until the required intensity is produced. When, having well-drained the plate, flow it with glycerine, pouring it on slowly at one corner, and seeing that in its course over the film it carries with it all spangles of silver left by the developer. This is the important point and the only trouble I have experienced is some of the metal silver becoming attached to the film so that no after washing would remove it. It is best to drain off this first coating and add a fresh lot of glycerine. Then place the plate, film side up, in a plate box so arranged as to hold the plates in a horizontal position.

If the dark tent used is of such a nature that the plate box may be kept within it, there is no need of pushing the development in the manner above described, but flowing with glycerine as soon as the first application of iron has done its work, and then inclosing in the plate box,—keeping it away from the light until it can be washed and the development proceeded with. I have made many pictures without any water in the field, but when I can I prefer to use water freely—that is where water can be got without any trouble. It is also economical in other cases to have a few ounces of water, not enough to wash the plates, but merely enough to flow over and drive off the spangles of metal silver before applying the glycerine, as water is the cheapest article of the two. I find that 16 ounces of water is more than enough for a long day's work on stereoscopic pictures. The glycerine does not check the action of the developer, but where iron is used there is no need to check its operation, as it is limited in its power as a developer; the glycerine keeps the film moist for a greater time than any syrup.

The only precaution to be taken is, that if a picture thus treated has been exposed to the light before completion, no silver must be used in the strengthening process, but having washed and cleaned the picture resort to bichloride of mercury to obtain the requisite degree of intensity.

Hoping my readers will not deem me inconsistent as the author of the glycerine process before washing, I would urge them to use it with prudence, observing the precaution above mentioned to insure good work,—and by all means if it can be got, and, if any kind friend can be called upon to help carry the fixings, to take with them a bottle of water,—it may be wanted to drink you know, a little will do the pictures no harm.—*American Journal of Photography.*

A CONTEMPORARY HOBBY.

BY THE AUTHOR OF "LORENZO BENONI."*

I don't know how it fares with you in London, but I know that we in Paris have a sorry life of it. By which *it* I do not allude to the frost, nor to the macadamized Boulevards, nor to the tightness of the money-market—no, nor yet to the indefinite rise of house-rents, but to a far worse nuisance—the cardomania. Ever since it has become the fashion to have squinting, ghastly photographs, instead of the true, plain, honest visiting-card—ever since it has become the fashion to make collections of these said photographs—above all, ever since the fatal invention of albums *ad hoc*, farewell peace! Whichever way you turn, requests for your portrait are levelled at you like so many guns. All is acceptable prey; indifferent features, respectable age, obscure position—nothing comes amiss to that greedy monster, Album.

I give myself as an example. I, socially speaking, one of the most insignificant beings in creation, had so many home thrusts to parry of late, that at last I was thrown out of the saddle. A lady did that for me—a clever and accomplished blonde—beware of blondes. She was doing me the honours of her album, and I was on the defensive. We came to an empty niche. She said pleasantly, calmly, decidedly, "That is for you." I did all a man can do—very little, I allow, when the adversary is one like my softly determined, smilingly implacable hostess—I laughed outright, found the joke excellent; then I became serious. She knew my habits—my dislike of all that makes a man a plaything, and so on. Grave or gay, it mattered not. Let the fair sex alone for holding to the point when it suits them.

"If, by New Year's Day," said the lady, "this niche is not filled by your photograph, I shall have been mistaken in your gallantry." I protested in favour of my gallantry; but surely she would grant me a respite, considering that just at that moment I was very busy—in all truth, overworked . . .

"Oh, sir," was the quick rejoinder, "if I were asking for a miniature, even for a sketch in crayons; but a photograph! a sacrafice of five minutes!"

Whatever my misgivings about the five minutes, we live, as everybody knows, in a chivalrous age, and, to use the words of a great man, I am a man of my times. So I bowed my head, whispered something about wishes being commands, and went my way. My last thought on going to sleep that night, my first thought on awakening next morning, was that I must go and have my photograph done.

When a tooth must come out, the sooner it is out the better. In compliance with this wise aphorism, I sallied forth in quest of a—I was going to say "dentist"—in quest of a photographer. No need to go far; every second door on the Boulevard boasted the name of one. Next to literature, photography seems to be the favourite vocation of those who have none. Let me see. Mr. Perlet, *chemiste photographe.* Too much by half. I shall have to pay for the chemistry. Mr. Perlet shall not have my custom.

Messrs. Verplick Candish. This sounds outlandish, but safer;—a first-rate establishment—at least, if one may judge by the outside. Behold a richly-carpeted staircase, a banister of gilt and red velvet with coloured crystal globes at intervals, red velvet *portière* concealing the sanctuary to which the gorgeous ascent led!—Who pays for all this finery? Never mind. I shall do my blonde friend's behest handsomely.

So up I went, and, raising the crimson drapery, entered an ante-room, midway of which I was met by a fashionably-dressed gentleman, who asked if I had come for *cartes de visite.* I replied, "Exactly so; for *cartes de visite.*" "Very well. Would I give myself the trouble to walk this way?" and the well-dressed gentleman passed behind a railed desk, while I took up a position in front of it. A voluminous ledger lay open on the desk.

"Will Monsieur give his name?"

As I had come for a portrait, and not for a passport, the request sounded strangely; nevertheless, I complied. Whatever may be my objection to giving my portrait, I have none against giving my name.

"Monsieur lives?" I said where I lived, and my address was added to my name.

"Monsieur has number 309," explained the gentleman; "Monsieur will be informed by letter of the day on which his turn comes."

"And when is my turn likely to come?" asked I.

"Impossible to fix a date; much depends on the weather, and other circumstances over which we have no control. I should say in a month—perhaps even in three weeks."

"In that case, have the goodness to efface my name," said I; "I must have my cards on the last of the month at the latest."

The gentleman was sorry; but at this time of the year . . The whole person of the speaker, eyes, eyebrows, shoulders, hands, were eloquent in protestation of the vanity of my wishes. So without further parley I bowed myself out.

I spent a full hour in new trials; and, believe it or not, fair reader, but I say only the truth when I say that nowhere, either for love or money, could I get the promise of a photograph of myself, under fifteen days. Now, as it was already the 18th of December, and my card fell due on New-Year's day, a fortnight's delay placed me in the physical impossibility of keeping my word.

My best course was to quit the more aristocratic daily lounges, and try some less frequented neighbourhood, which possibly the fashionable epidemic had not yet attacked. With this hope I repaired to the Palais Royal. Here again there was too much of a good thing—rows and rows of photographs, and photographers' signboards stared at me from every corner. Like Yorick in search of a passenger from whom he might ask his way, I scanned the outward features of perhaps a dozen establishments, without seeing aught that could influence my choice one way or the other. At last I perceived this N.B. attached to a photographer's name. "Up at the seventh story." Eureka! cried I; no danger of competition from the lame and asthmatic here,—and up I climbed. I was received by a lady. I took it as a good omen. Women are more easy and pleasant to deal with than men. "Madame," said I, as soon as I could recover my breath, "I wish to have some *cartes de visite* done."

* We condense from an article in *Macmillan's Magazine* the above amusing sketch of an episode in the history of the "cardomania" in the French metropolis. The extract has been marked for insertion since April, but has been delayed from lack of space.

"Certainly," replied the lady, "how many do you— ?"

"Excuse my interrupting you," I continued, in an unsteady tone, "but I should like to know how soon you can take my likeness."

"Immediately, if it suits you—(I could have hugged the speaker to my bosom for these blessed words)—that is," pursued she, "should the light serve, which I rather doubt—really we have no afternoon. At all events I will go and inquire of my husband."

Alas! the light, such light as it was, December light you remember, did no longer serve. Such was the fiat with which the lady emerged from the glazed door of an adjoining closet, evidently the photographer's workshop. But, if I would return on the morrow about midday, I might make sure of having my photograph taken.

I was punctual to my rendezvous next morning. At three minutes to twelve by the time-piece of my photographer (to be) I had taken up a position in the lilliputian waiting room.

"Very poor light," observed the artist by way of salutation. "Let us make the most of it as it is, by looking sharp," said I. The man being apparently of my opinion, a few seconds were enough for him to suggest, and for me to assume a becoming attitude in front of the four cannon-like tubes which were to reproduce my respected person four times at once. "We are going to begin—perfect immobility if you please; keep your eyes steadily on the handle of the door; there." The operation began, and was done, or not done, in less than five minutes. So far my fair-haired lady was right.

In course of time, the photographer reappeared. "*Manqué*," said he, with a rueful face, "in all my experience I never saw such another abominable day for light," exclaimed the photographer. "However," he added, "suppose we try again." "Let us try again," said I; "is there any reason against my keeping on my hat and great coat? I am half frozen." "It would be a certain failure if I did so," was the answer; and so I had to part with my hat and upper garment, and sit in the draught unprotected.

Had the sacrifice only availed! but no, the second attempt was not more fortunate than the first. "It was enough to drive a man crazy," declared the perplexed artist, "all had come out beautifully, but no head! Useless to make any more attempts that day. Would I call again on the morrow, before noon." Of course I would; I had no choice but to do so.

Contrary to my anticipations, which were of the blackest, everything on the morrow went as smooth as oil. I had to wait comparatively but a short time; the light was tolerably favourable, and the likeness--so at least averred the photographer—had come out capitally. He promised that my *cartes de visite* should be sent to me on the 26th (it was then the 20th); I left a card with my address, and went home to nurse my cold in peace, thankful at heart at having got rid of my incubus on such easy terms.

The 26th came and went; and so did the 27th; and heaven knows how many more days might have come and gone without my giving a thought to the *cartes de visite*, for I happened to be very busy at the time, had not chance thrown me on the evening of the 28th in the way of my fair persecutress of the "five minutes" at the house of a common friend.

The first thing I did the next morning was to go and see after these blessed cards.

"Madam," said I to the lady, in whom I had seen a benignant influence on my first visit to the photographer of the Palais Royal, "as you have not kept your promise of sending me my *cartes de visite*, I have come for them myself."

"Your cards, sir?" replied the lady, evidently perplexed; "dear me, then you have not received my letter."

"I have received no letter," said I.

"Then you are ignorant of the accident which has happened."

"Accident? what accident?" cried I.

"Well, your glass, I am pained to the heart to say, somehow or other, was thrown down, and shivered into atoms."

I was literally struck dumb by this unexpected catastrophe. I gave a deep groan. The lady continued,—

"I did not lose a minute in writing to you. I am sure I made no mistake, for " (fixing her eyes on me) "you are Mr. Wolf, are you not?"

("Mr. Wolf!!!")

"You live in the Rue des trois Epées?"

("Rue des trois Epées!!!")

"I copied the address from the card you left us. Where has it got to?" searching among several which were stuck in the frame of the mirror. "Ah! here it is; I knew I was right."

I cast my eyes on the card she presented to me, and read, "Mr. Wolf, Pedicure, 70, Rue des trois Epées." It wanted but this. To have to begin, *ab ovo*, and to pass for a Pedicure into the bargain!

The lady was right; alas! the mistake was entirely my own. The fact was, as I explained to the lady, that I had a—I beg your pardon—a corn, which made me suffer martyrdom. One of my friends advised me to apply to an excellent pedicure, whose address he would send. He sent it; and, as my evil star would have it, his note, inclosing Mr. Wolf's card, was delivered to me by my *concierge* just as I was going out on my third photographic expedition of the 20th. I put the card into my waistcoat pocket, and inadvertently gave it to the photographer instead of one of my own.

I had the cause to be thankful that I was yet in time to repair my blunder.

"Madam," said I, with as much pathos as I could put in my voice, "I am pledged to give my *carte de visite* on New-Year's day; pray, madam, help me to do so. Name any price you think proper, but let me have my card."

"My dear sir," replied the lady, "be convinced that I feel for you; indeed I do; but you ask an impossibility. We are literally sinking under the weight of work; my husband is positively made ill by it. We had to refuse a good half of the applicants for cards, and—I would not own as much to anybody else, but really your situation distresses me—and even of those we have accepted, we shall be obliged to disappoint the greater number. Just take a peep into the waiting-room, will you? Full as an egg (and so it was). You see I speak the truth; why should I not? It is our interest to please the public—"

A moment of reflection convinced me that there was but one course left for me to try. I beckoned to a cab, drove home, packed my carpet-bag, drove to the Strasburg Railway terminus, and took a ticket for Bar-le-Duc.

Why for Bar-le-Duc? Because of all the places on this terraqnean globe Bar-le-Duc was the only one where I had a fair prospect of having my photograph done—in other words because there resided in Bar-le-Duc a friend of mine who was an *amateur* photographer, and on whose assistance, if alive and capable, I knew I could rely.

If ever a man was surprised at the sight of another, it was my friend at sight of me. "Just like me," he declared, "he never—"

I hastened to explain the cause and object of my present visit.

"But, my dear friend," he objected, "you could not have chosen a more unfavourable moment."

"Did I say that I had chosen it? A bit of straw driven by the wind is not more passive than I am in this affair."

"With the snow falling in this way," he pursued, "no hope of doing anything tolerable."

"Let it, then, be something intolerable," said I.

"Really, you are not in a fit condition to have your likeness taken; you want rest. Go to the glass and judge for yourself. You look like a ghost."

"Ghost or scarecrow, it does not matter; only for pity's sake take a photograph of me at once. I must be in Paris to-night; I have a paper to finish, and to send off by to-morrow's post."

Satisfied that he had done all in his power to enforce the claims of art, always foremost in his eyes, my friend, in spite of the snow still falling, and the false light, undertook with a good grace the task I demanded of him. It required all his skill and patience to bring it to a plausible conclusion. The likeness obtained after two hours' hard work, bad as it was, he pronounced to be as good as could be hoped for under the circumstances. It was far from a flattering resemblance certainly, but for that I little cared. I should without fail receive a copy by post, on New Year's day. I might rely on his punctuality: thereupon, with heartfelt thanks, I departed.

The same gentle influences which had accompanied me from Paris to Bar-le-Duc—snow, wind, cold, &c. &c.—favoured my return to Paris. I reached home more dead than alive. I tried hard to finish the paper I had engaged should be forwarded on the morrow, but in vain; I had to send instead an apology, which brought me in due course a good blowing up from the disappointed editor—one of the many perquisites of the trade.

The next day—the last of the year—was, I sincerely believe one of the most uncomfortable days of my life. Dire anxiety weighed on every hour of it. Do what I would, I could not bring myself to believe that the card from Bar-le-Duc would arrive on the morrow. Something must happen to it. What had occurred before might occur again; nay, possibly it was quite in the ordinary course of photographic events that the plate or glass should break, or, if the photograph was sent, it might be smashed by a railway accident, or the envelope containing it be dropped by some careless postman. Anything seemed more likely than that it should arrive safely.

It did, though to my inexpressible relief, and I hastened to carry it myself to its destination. The fair lady was from home; so I left it, carefully wrapped up, and addressed, with her *concierge*: and then, for the first time for fourteen days, I breathed freely.

In the evening I received the following note:—

"I regret very much to have missed seeing you this morning. Thank you for your card. It does not entirely satisfy me. You know I am extremely particular about my photographs; so do not be surprised should I ask you for the sacrifice of another five minutes. We will speak of that. Come and take a family dinner with us to-morrow, at half-past six. Mr. Paul, and Mme. Lorry, will be our only other guests. By the bye, they both think your likeness good, and mean each of them to beg you for one. So be amiable enough to bring some more of your *cartes de visite* with you. *A demain donc.* Believe me, sans adieu. Yours sincerely, ———."

The perusal of this note threw me into despair. And so, all the wear and tear of mind and body, all my loss of time, all my disbursements, were to go for nothing; to leave me at the point from which I had started! the stone I had lifted in the sweat of my brow recoiled on me! I took up the pen, *ab irato*, to say what?—anything but that I accepted the invitation—to say that I was ill, that I had been called away by a telegram, that —that—but of what avail any excuse? To procure me a respite of a week—say of a month, and then? Why, all the botheration would have to be gone through anew. No, there was nothing for it. To go and settle in the backwoods of America, or to take the world as it was, hobbies included, such was the dilemma which rose before me, clear and defined; there was no escape. It was for me to choose. I pondered long, pen in hand, and then wrote this answer:—

"Dear Madam,—I accept, with thanks, your kind invitation for to-morrow. I regret that my *carte de visite* does not meet with your approbation; however, I am at your service for any number of experiments in the same line—in fact, until the result shall satisfy you. I am much flattered by the wish expressed by Mme. Lorry and Mr. Paul. I have written for an immediate supply of half-a-hundred copies of my card to meet the requests of my friends. Believe me, dear madame, ever yours, sincerely obliged, ———."

Proceedings of Societies.

North London Photographic Association.

The first meeting of this society, after the summer recess, was held at Myddelton Hall, on the evening of Wednesday, September 18th. G. Shadbolt, Esq., in the chair.

The minutes of the last meeting having been read and confirmed, the following gentlemen were elected members of the society:—Messrs. A. Seeley, Biddle, H. Simpson, H. J. Vachell, J. C. Brown, Gandy, and Captain Herne.

The Chairman introduced to the notice some specimens, chiefly illustrating the characteristics of different lenses, amongst which were some produced by Grubb's aplanatic and portrait combinations, and some by the new American lens, by Harrison, which has been stated to include an angle of 90°.

Mr. Dallmeyer showed some specimens produced by his triple achromatic lens.

The Chairman observed, in relation to the pictures by the American lens, that no accurate data had been furnished from which the angle could be calculated, but that any one familiar with optics, would readily conclude that the claim made of including an angle of 90° was entirely erroneous. The entire diameter of the picture did not appear to embrace an angle of more than 60°, and if cut in the usual way not more than 45° would be included. The lens with which the circular specimen of about five inches diameter, was produced, was stated to possess a focus of 2½ inches. That was doubtless from the back lens, and not a word was said about the distance between the lenses, so that nothing was suggested as to the equivalent focus. He had recently had a letter from Mr. Seeley, who stated that he was unable to give any very definite information, as Mr. Harrison declined to permit any inspection of the lens at present.

Mr. Dallmeyer observed, in relation to the question of a wide angle being included by an ordinary view lens, he wished it to be understood, that by using a sufficiently small stop any single lens might be made to give definition over a very wide angle, but no matter what form such a lens might have, it must present distortion of the marginal lines.

The Chairman then read a communication from Dr. Maddox, detailing some experiments with albumenized plates for transparencies. He had tried the effect of various kinds of acids added to the albumen and to the developer, and had come to a conclusion that phosphoric acid gave the richest tone.

Mr. Barnett exhibited a very good transparency by the resin process.

Mr. Hislop had recently been trying the resin process, and was so well satisfied with it, that he has given up all others. He used half-a-grain of common resin to each ounce of Ponting's collodion. His bath was slightly acid, just the same as he used it for wet plates, and one peculiarity of the negatives was their similarity to those produced by the same collodion when wet, with perhaps a little more detail.

Mr. Hill observed that one of the claims made for the resin process was its superior sensitiveness. Had Mr. Hislop found it so?

Mr. Hislop had not found it more sensitive than the other dry processes he had tried; but he thought that with the same exposure it gave more softness and half tone. Its chief advantage was simplicity, thus effecting a great saving of time in the preparation. He placed each plate, on coming from the nitrate bath, in a dish of water, and then washed it well under the tap, and allowed it to dry spontaneously. The plates were developed in the same manner as wet collodion, and came out very rapidly.

The Chairman said that the Abbé Despratz, in originally suggesting the process, had laid much stress on the film adhering well to the plate, a quality, which, however, had not been found to exist in practice.

Mr. Hislop said the chief difficulty he had found was the tendency to dry during development.

The Chairman said that probably a little glycerine added to the developer would be found to obviate that difficulty, if it did not at the same time cause fogging.

Mr. Hill asked how long Mr. Hislop had found the plates keep.

Mr. Hislop said he had kept some for six weeks without noticing any deterioration.

The Chairman called attention to a new and very simple contrivance for holding the plate during the process of development, recently brought out by Mr. Solomon.

Mr. G. Wharton Simpson had tried this plate-holder, and could speak in the highest terms of its value. It held the plate firmly and prevented the danger of stains, either on the plate or the hand.

Mr. Morley showed some negatives from plates prepared as suggested by Dr. Ryley. The plates were, after sensitizing and washing, covered with diluted albumen, thoroughly washed and dried. They were then coated with a one-grain solution of tannin, or gallic acid, and again dried. All the negatives were very clean, brilliant, and perfect; that coated with tannin was thought to possess a little advantage in sensitiveness.

Correspondence.

FOREIGN SCIENCE.

[From our Special Correspondent.]

Paris, 25th September, 1861.

M. Steinheil, of Munich, has succeeded in constructing another new lens on the principles laid down by the celebrated mathematician Gauss. His previous effort was noticed in the Photographic News about a year ago. Gauss had shown that it was possible to exactly combine two rays of different refrangibility, both for the centre and for the edges of the lens, while in ordinary lenses only the mean rays unite with a ray of different refrangibility, proceeding either from the centre or from edges, hence results chromatic aberration, which increases with the aperture. Gauss, in his new construction, had succeeded in removing this objectionable aberration, but there remained another apparent in the mean rays. Besides, the radius of curvature in the new lens is less than a tenth of the focal length, while in Frauenhofer's lenses, it was at least equal to a third of the focal length. These circumstances were calculated to inspire doubts as to the practical value of Gauss's lens. Attempts at constructing it failed. But the cause of failure arose from a misconception of the opticians. The calculations of Gauss refer generally to the whole extent of the visible spectrum; but to render them practicable, it was necessary to limit them to the principal mass of the luminous rays. The aberration of the mean rays could afterwards be destroyed by suitably selecting the thickness of the lenses; and it is by regarding all these considerations that M. Steinheil has at length succeeded in obtaining a lens which possesses all the qualities anticipated by Gauss. The first lens of this kind which has emanated from the workshops of this optician is an objective of 36 lines diameter, with a focal length of 46 inches. It well sustains a magnifying power of 300 to 400 times. This instrument has lately been examined by MM. Peters, Klinkerfues, and Listing, and they pronounce it very superior to a Frauenhofer of the same dimensions. This objective, although its radius of curvature is only double that of its diameter, is perfectly achromatic and aplanatic. M. Klinkerflues has been able to distinguish with this instrument, and also with a telescope of 49 lines diameter, the very indistinct companion of β in Orion, which he could never discover through a five feet Frauenhofer. M. Steinheil has also executed some lenses in Gauss's formula, with a much less focal length than that of ordinary objectives of the same aperture and he is in hopes of obtaining instruments much more powerful than the old ones, without its being necessary to increase the length of the tubes.

M. Eugene Garneri announces the discovery of a mineral collodion, which possesses extraordinary sensitiveness, and which appears also to promise retaining its sensibility for a very long time. His plan consists in enclosing the sensitizing agent (iodide of silver) not in a film of organic matter, changeable like pyroxyline, which is left by the evaporation of the ether of the collodion; but in a film of *silica*, that is to say, in one of the most unchangeable substances known.

This mineral collodion is prepared in the following manner: to a suitably diluted solution of silicate of potassa or soda, add sufficient diluted hydrofluosilicic acid to completely neutralise the liquid to test paper, or what, perhaps, is the better, to leave an exceedingly feeble alkaline reaction; a precipitate of alkaline hydrofluosilicate is produced, which floats in the liquor, which at this point is only an aqueous solution of silica, and remains perfectly fluid for several minutes, provided *the* alkaline silicate has been dissolved in a sufficient quantity of water.

To this liquor add a few hundredth parts of such soluble iodide as may be preferred, agitate the mixture so as to produce rapid solution, and then pour the liquid on a good filter.

In the course of a few minutes we have an aqueous iodized solution of silica, which serves to coat glass plates nearly in the same way followed for collodion. The glass plates are then arranged upon a perfectly horizontal plane; it is not necessary to wait for complete dessication, the operation is completed when the liquid has taken the consistence of a sufficiently firm jelly. When the siliceous coating attains the desired condition, it is sensitized, exposed, developed, and fixed, almost exactly in the same manner as wet collodion, with this advantage, that the plate, when sensitized, may be dried, and kept in the dark always ready for exposure.

Photographers who employ iodide of potassium or of sodium can prepare the silicious liquor by merely adding hydriodic acid to a solution of silicate of potassa or soda.

M. Garneri promises further details on the *modus operandi* on a future occasion.

M. Sahler states that he has obtained an instantaneous collodion, by employing iodide of iron in the nascent state, produced in the collodion itself. The results are always certain and superior to those obtained from the employment of the ferric iodide of commerce. He rubs up into a fine powder in a Wedgwood's mortar, some sulphate of protoxide of iron, the equivalent of which is 139, he also reduces to a fine powder some iodide of barium, the equivalent of which is 195. By mixing equivalent weights of these two salts in a suitable quantity of ether, double decomposition takes place; the iodide of iron remains dissolved, and the sulphate of baryta is precipitated. When filtered and added to the necessary quantity of gun-cotton, the collodion is ready for use.

PHOTOGRAPHY IN GERMANY.

Elberfeld, 16th September, 1861.

Dear Sir,—Since I last wrote to you I have received from several persons accounts on Laborde's addition of free iodine to the silver bath. They all agree with me as regards the excellent working of the baths treated in this manner. I need scarcely say, however, that I found the bath a little acid from liberated nitric acid. Dr. Schnauss writes to me about this matter: "In order to bring a fresh nitrate bath into working order there is no better means than to add some tincture of iodine instead of acetic acid. I must wonder however that the Abbé commits such a chemical fault in saying, 'One should think the iodine would combine with the silver, and so liberate nitric acid. But it is not so, the bath remains quite neutral even when heated.'"

The most simple chemical experiment teaches the contrary! Add one drop of alcoholic solution of iodine to a solution of neutral nitrate of silver in water: immediately a precipitate of iodide of silver falls down, and the solution shows an acid reaction from liberated nitric acid. It cannot be otherwise on any known chemical principles. It is therefore only the liberation of a small part of nitric acid which produces this favourable change in a fresh bath, which tends to give fogged and feeble proofs.

Another new process, that of Professor Balsamo, described in No. 154 of the Photographic News, has not as yet proved its applicability. It has been found impossible to get a trace of an image upon the paper prepared with the indicated cupro-phosphor-hydrochloric solution. One experimentalist believes phosphorus to be insoluble in hydrochloric acid. Should we, nevertheless, succeed in producing pictures in this manner, I think the process can never come into general practice, the phosphorus being a poisonous substance, and the sulphuretted hydrogen possessing such a disagreeable smell.

Recently much has been said about enlarged photographs of microscopic subjects. Professor Gerlach, of Erlangen, has sent some photographs of this kind to the Royal Academy of Berlin, with a description of his process. He makes first a microscopic picture of the small subject with a microscope, the construction of which he promises to describe at another opportunity. The small microscopic picture is enlarged by a quarter-plate portrait lens. The author has enlarged gubbings of Hipparchia Fanira, 1500 times.

Another well-known physicist, Professor Dr. Von Babo, of Frieburg, has sent me some stereoscopic pictures (in the usual size) of microscopic subjects. The most interesting is the enlarged copy of a fungus in the flower of oak, (Lohbluthe), having not more than a millimeter in diameter; the stereoscopic effect of these pictures when seen in the stereoscope is very remarkable; the ramification of the fungus appears like a large tree.

Dr. Schnauss publishes in the journal *Photographisches*

Archiv, an account on Major Russell's tannin process. For nearly five years past, a zealous follower of Taupenot's process, he now gives the preference to the tannin. The following are some observations he has made on it.

When pouring the tannin solution on the collodionized, silvered, and washed plate, often the whole film becomes brown; the only preservative against this is to wash the plate with salt solution and afterwards with water before pouring on the tannin solution. By this process all free nitrate of silver (which can *never* be completely washed out of the collodion film) is decomposed. The negatives become then very dense and pure.

When one takes the plate out of the camera back, the whole picture often is visible. This proves an important developing power of the tannin. The negatives tend after longer development, to become positive, the transparent shadows begin to darken. This inconvenience is mostly produced by the deficiency of acid in the pyrogallic acid solution. If sufficient of the silver solution—which contains the citric acid—is not added to the pyrogallic, the transparent parts of the negative will soon be fogged. For this reason I recommend to have a separate solution of citric acid in water which may be added, when necessary, to the pyrogallic solution.

The blacks of the negative become yet more dense than in the wet collodion process. This is one of the greatest advantages of the tannin over all other dry processes. Also the pictures are very clean, and without spots. If one exposes only a short time in the camera, one obtains very beautiful direct positives, which possess, after being varnished, a fine gloss like daguerreotypes.

I sometimes found the formation of small, black, round spots in the film, without any exterior cause.

Beyond the *utmost cleanliness* I recommend yet the following points for consideration:—1. The coating of the glasses with gelatine.

2. Spontaneous drying, and then the drying by artificial heat; and, finally, cooling of the plate before the collodion is poured on.

3. The coating of the plate with diluted salt water, after the washing off of the nitrate bath, and repeated washing with water before pouring on the tannin solution.

4. *The rapid and homogenous drying of the tannin film.*

5. The *rapid, homogenous* wetting of the plates before the development.

6. The just proportion between pyrogallic acid and nitrate of silver, conforming to a long or short exposition.

The composition of the silver bath and collodion is not very important, provided they give good dense negatives in the wet way.

If during the development too much silver solution has been used, especially when the exposition was short, one obtains often too great contrasts between light and shadow. The pyrogallic acid solution should always be fresh prepared by diluting some alcoholic solution of this substance with water. The alcoholic solution can be preserved during some time.

For some time past I use green glass in my dark-room instead of yellow, and find it very profitable, because one can better see and judge the density of the negatives. I can work in this room, with the most sensitive and harmonized chemicals without a trace of fog. I remark that no direct, only reflected light falls through the green windows.

PAUL E. LIESEGANG.

Photographic Notes and Queries.

PHOTOGRAPHIC VESSELS.

SIR,—Having experienced the advantages of vessels constructed of the highly carbonized compound of caoutchouc, termed *ebonite*, for chemical and electrical purposes; I may be allowed to call the attention of your readers to the valuable properties which such vessels would possess in a photographic point of view. Ebonite appears to unite in the most perfect manner, the negative chemical properties of glass or porcelain, and the non-liability to fracture of gutta-percha. It is attacked only by the strongest acids, is free from the tannin and other uncarbonized vegetable matter contained in gutta-percha, and is consequently without action upon the salts of silver, and other metals. Moreover, by immersing vessels of ebonite in the water or salt-water bath, solutions may be heated in them to a temperature over 212° Fahrenheit, or maintained at any required degree of heat. These advantages cannot, I think, fail to secure the adoption of *ebonite* for vessels required in photographic manipulation.

D. G. FITZGERALD.

September 23rd, 1861.

[We shall be glad if our correspondent can give us information as to the manufacturers of this material. We think it very probable that it might be found of much service in photography, and should like to try it.—ED.]

THE ELECTRIC TELEGRAPH ANTICIPATED.

5, *Aberdeen Park, Highbury, Sept. 21st.* 1861.

DEAR SIR,—In reading an old number of the *Guardian*, which was published on Tuesday, July 28th, 1713 (148 years ago) I found the following passage, and thinking that it might not be unworthy of notice in your valuable pages, I hope you will be kind enough to insert it.

"Strada, in the person of Lecrotius, gives an account of a chimerical correspondence between two friends by the help of a certain loadstone, which had such a virtue in it, that if it touched two several needles, when one of the needles so touched began to move, the other, though at never so great a distance, moved at the same time and in the same manner. He tells us, that the two friends, being each of them possessed of one of these needles, made a kind of dial-plate, inscribing it with the four and twenty letters of the alphabet, in the same manner as the hours of the day are maked upon the ordinary dial plate. Then they fixed one of the needles on each of these plates in such a manner that it could move round without impediment, so as to touch any of the four-and-twenty letters. Upon their separating from one another into distant countries, they agreed to withdraw themselves punctually into their closets at a certain hour of the day, and to converse with one another by means of this their invention. Accordingly, when they were some hundred miles asunder, each of them shut himself up in his closet at the time appointed, and immediately cast his eye upon his dail plate. If he had a mind to write anything to his friend he directed his needle to every letter that formed the words which he had occasion for, making a little pause at the end of every word or sentence, to avoid confusion. The friend, in the meanwhile, saw his own needle moving of itself to every letter which that of his correspondent pointed at; by this means they talked together across a whole continent, and conveyed their thoughts to one another in an *instant* over cities or mountains, seas or desarts."

To those who are acquainted with the working of the common telegraph, and also of that invented by Professor Wheatstone, this will prove doubly interesting. To those who are not, a little explanation will be necessary. In the ordinary electric telegraph, the letters are indicated by so many movements of the needle one way or the other, viz., either side of a fixed point. But in Wheatstone's magneto-telegraph the needle points to the letters of the alphabet, which are placed *round* the dial in the manner described in the passage quoted above; and the electricity is gained by the rotation of a *magnet*.—I am, yours respectfully,

H. COOPER.

ARTIFICIAL LIGHT FOR PHOTOGRAPHY.—A method of applying artificial light to photographic purposes was recently patented, but has not been proceeded with. It consisted in combining the use of electric light or of gas light with Mortessier's mode of obtaining positives or positive photographs, photographic proofs, or impressions. By these means the artist can photograph without being dependent on solar light, and the artificial light used in this invention can be controlled, so that proofs may be obtained of various effects, and faulty negatives corrected; effects can be rendered more distinct by throwing an excess of light on parts where it may be necessary, and darks can be toned down by shutting off or intercepting the luminous rays by a screen.

Talk in the Studio.

The Holiday in the Woods.—An exhibition of works of art was recently opened in connection with the Cornwall Polytechnic Society. We notice that a silver medal was awarded to Mr. H. P. Robinson of Leamington, for his Holiday in the Woods, with which our readers are familiar. An award of £1 was also made to the Rev. F. E. Guttross of H. M. Ship Russell, for a series of stereoscopic views.

Panoramic Photography.—We have just been favoured with an inspection of a series of the most perfect negatives we have ever seen, taken by Mr. Sutton, in Jersey, on curved 9 by 7 plates with the panoramic lens. The angle included was from 90° to 100°, the subjects well chosen, the definition exquisite, and the negatives apparently without a spot or defect of any kind. Nothing could so effectually prove the facility and ease with which curved plates are manipulated than an inspection of these negatives, which are as free from mechanical or chemical defects as the best negatives on flat plates we have seen. Pictorially they are very charming, at least one of the number having fine natural clouds.

The Exhibition at Florence.—The Correspondent of the *Daily Telegraph* speaking of the Exhibition of Works of Industry and Art at Florence, says:—"The photographic gallery, already of an alarming size, is growing daily more extensive. Among some thousands of photographs there must be a good deal of rubbish, and, above all, there is an excessive collection of portraits, "*of no value to any but the owners.*" But there is also very much to admire, and I think photographers (generally an erratic race) might learn something by wandering to Florence. Among the best, I will mention two or three; but there is as yet no catalogue from which I can give the artists' names. The finest portrait is a full-length picture of the "King," in plain clothes. It is not painted, as I have seen large photographs in London, but remains in the usual unbecoming black and white; nevertheless, it is the King himself, the best likeness and the easiest *pose* of the many thousand effigies of Victor Emmanuel that one sees in Italy. There are some splendid architectural pictures, and some landscapes and portraits (done with wet collodion) of Allinary, of Florence. Duroni, of Milan, is also very strong, and there are many (nameless as yet) excellent views of Rome and Venice, two cities built to be photographed. An amateur, Mr. William Warren Vernon, displays one of the best executed and most interesting collections. Then there are photographs on cloth, some coloured in water colours, none in oil, and portraits of all sizes, shapes, and colours; and he must be a hermit and a solitary who cannot detect the likenesses of some dozens of his friends.

To Correspondents.

*** Messrs. Hope and Co.—We are requested to state that the firm of Messrs. Hope and Co., of Hammersmith, conduct business as usual. The announcement in answer to a correspondent in our last that the firm had ceased to exist was an error, the result of a misconception.

H. Cooper, Jun.—It is somewhat difficult to deal with a bath that retains a deep colour in spite of kaolin, animal charcoal, chloride of sodium, and citric acid. You may possibly find it yield to influence of light. Render it neutral by the addition of oxide of silver, and then expose to strong sunlight. The organic matter, to which the colour is due, will be thrown down, and you will probably by that means get a clean bath. Add a little nitric acid before using again. 2. The reason your cotton dissolved on trying the new sample of nitric acid was the presence of a larger proportion of water than you had before; the acid was, in short, weaker. The remedy is the addition of a larger proportion of sulphuric acid, the exact amount of which must be found by experiment. There are several varnishes which dry without heat. We have frequently used that sold as "crystal" with advantage; but it is not very hard, and requires care. Your interesting extract shall appear.

W. G. G.—In painting a screen with a landscape, for backgrounds, use oil colours mixed with as little oil as possible, using turpentine instead. Or use distemper colours; that is, mix the pigments with water and a little size. Unbleached sheeting calico is the best material for the background. 2. The best plan is to neutralize your chloride of gold as you require to use it; if, however, you have merely made it neutral it will keep very well in that state. In the passage to which you refer a few words have been interpolated by accident.

Builsah.—The provisions of the Amateur Photographic Association will, we understand, extend to India. We have inquired and are informed that they cannot undertake any expense or responsibility regarding the carriage of the negatives. The best plan, if others desire to join, would be for several gentlemen to send their negatives at one time. As yet we do not know much about the working of the system. We will let you know what we learn of its working when it has been established a short time. 2. A very stable iodizer, giving good results, is as follows: iodide of sodium 2 grains, iodide of cadmium 2 grains, bromide of cadmium from half a grain to a grain, dissolved in the smallest quantity of alcohol, to each ounce of collodion. 3. The lenses you have may be used for enlarging; the only additional apparatus you will require is a large camera, with a long extending body. The simplest plan is first to produce a transparency on glass from the original negative, and then an enlarged negative from the transparency. The process is too long to describe in detail here; but a little thought and experiment will enable you to succeed. Possibly we shall revert to the subject shortly. 4. On the whole we prefer the collodio-albumen process, and for India it would probably answer better than other dry processes. We shall have pleasure in receiving an account of your trip.

H. B. Y.—You do not state whether you mean collodion positives or prints from negatives. If the former, glass is the best material, if you are accustomed to cutting it to fit lockets; if not, use the enamelled iron plates. 2. In making oxide of silver continue adding the alkali until all the silver is precipitated. There is no danger of adding too much, as all excess is afterwards washed away. 3. You may make chloride of gold from the "gilder's dust" you have, by adding acid in the usual way, more than once described in our pages.

J. M.—A stereoscopic negative can be enlarged to 12 by 10 without serious loss. We cannot tell you the probable cost, nor the best place to get it done. We believe Mr. Samuel Fry, of Forest Hill, undertakes such commissions, you had better write to him. There are several persons engaged in enlarging by means of the solar camera for the profession, but we cannot tell you all their names. We may mention, in addition to Mr. Angel of Exeter, Smyth and Blanchard of London, and Webber of Taunton. An enlargement from a small print is comparatively worthless, it should be from the negative. A landscape lens may be used for copying. We are glad to help you with any advice in the pages of the News, but our engagements prevent us from writing long private letters, especially by return of post. Your print is interesting, but slightly under-exposed.

Robert H. Courlang.—Messrs. Beard and Sharp's process of printing on ivory is a secret, but we believe it is not patented. We do not think there is anything to prevent your practising and bringing a process of your own before the public. We shall be glad to see a specimen.

Mineral Carbon.—Cyanide of calcium is obtained in the form of an aqueous solution, by saturating hydrocyanic acid with hydrate of lime, and filtering. To the filtrate add dilute hydrocyanic acid until it no longer precipitates a neutral solution of sulphate of magnesia. Cyanide of calcium is decomposed with the utmost readiness, losing hydrocyanic acid by the action of the carbonic acid of the air, or by boiling. It can only be obtained in the solid form by evaporating the aqueous solution *in vacuo* over oil of vitriol.

D. L. I. is thanked. The hint shall appear.

R. Cooper.—We will write.

A Young Beginner in Photography.—A reasonably good equipment of apparatus with which to commence photography may be had for about £10. Sets of apparatus for less sums are advertized, but if you can afford it, don't get anything too common. A respectable dealer will best advise you. Most of the manuals for beginners give a list of requisites for a beginner. See that recently published by Mr. Hughes. We cannot mention the names of particular dealers here. The Photographic News Almanac for next year will be ready in November. A list of all photographic papers ever published would occupy too much space to publish here.

J. W.—Many operators state that they do not find any bad results from immersing plates in the bath which have a thin coat of albumen under the collodion. Some recommend coagulating the albumen, either by boiling water, protosulphate of iron, alcohol, &c. Our only experience in the matter leads us to discard the practice.

Francis Player.—The cause of your failure is simple. The cotton dissolving is the result of acids *too weak*, not too strong. Your acids are much too weak; you may try them in the proportions you state, but without any water. In the second formula, as you state it, you have taken rather more than a third of the proportion of nitre, and only one-sixth of the fluids, and of course obtained a paste instead of a fluid. The cotton will do perfectly. See recent articles in our pages on this subject in the "Dictionary of Photography." Try the formula we recommend, and you will not fail.

F. Lane.—Unless you can supply us with a piece of the glass, we cannot well assist you, as a large pane is inconvenient for use with the spectroscope.

T. R. H.—If iodine be applied to the silver stains on a cloth coat immediately, and then cyanide or hypo, they may be removed. But if they have been done some time, we fear there is no chance of removing them.

W. Henry.—The stains from the draining of the silver solution in wet plates, long kept or exposed, are very troublesome. They are more frequent with an old bath than a new one. The use of an alcoholic collodion lessens the probability of their occurrence. The only certain method of preventing them which we know, is to wash the plate before development with a small quantity of distilled water, which should be added to the developer. We have generally found this answer.

Wm. Bartholomew.—We shall have much pleasure in trying a few plates if you send them. With the characteristics you describe the process must be very valuable.

H. W. B.—The use of a bath with too much acid, or of an old collodion, for collodion positives, will have a tendency to produce excess of contrast in the picture. The details in the blocks will come out very tardily, even when the face is fully done. If you develop in a dish you must often renew the solution, as its continued use over and over will weaken it, and so cause it to develop imperfectly. Possibly your bath is getting old and weak. A very acid bath causes the film to have a tendency to leave the plate.

Several letters in type are compelled to stand over till next week.

Braisueeth Avoia, Narberth, James Tulley, G. Smith, J., G. and J. H. G., Caxton, and others, in our next.

R. Harmer.—We have received the paper, and will take an early opportunity of trying it.

Advertisements and Communications for the Publisher for the current number, to be addressed to the Office, 32 Paternoster Row, not later than 3 o'clock every Thursday. Post-Office Orders are to be made payable to Mr. Thomas Piper, at the Money-Order Office, St. Martin's-le-Grand.

THE PHOTOGRAPHIC NEWS.

Vol. V. No. 161.—*October* 4, 1861.

PROTECTIVE TAXES FOR PHOTOGRAPHY.

Our columns have recently been the vehicle for expressing a most unusual desire—the desire for taxation. Whilst a large portion of the intelligence and energy of our day has been directed to the removal of all fiscal impediments to progress, and the promotion of free-trade, it is somewhat startling to find any members of a class proposing that they themselves shall be taxed by the State. The desire for protection is not unusual, but it generally finds expression in pointing out how somebody else should be taxed; how art, industry, commerce, the State, may be benefited by imposing taxes on some other and competitive branch of trade. But here the taxes are desired for personal application.

The letters of Mr. Swatridge in a recent number and in this, and the letter of W. B. N., in another column of this issue, suggesting taxation for photography, each in different directions, are but the expression of a desire to be protected from unscrupulous competition. We think, however, the means indicated are wrong in principle, and would be inefficient in practice. Let us consider both plans briefly, in detail.

Mr. Swatridge proposes, in order to suppress the vile dens where the art is disgraced, and its practice simply a vehicle for extortion, that a yearly tax, for a licence, be imposed upon all who practise the art professionally. Such an idea implies at the outset a money estimate of intelligence and ability. Our correspondent may not intend it in such a sense, but it is nevertheless implied in it. The idea is therefore, most erroneous and unfair in principle: for centuries past that notion, at one time entirely interwoven with all Governmental schemes, has been gradually undergoing the process of elimination, and it would scarcely answer to return to it in reference to photography. It would be entirely inefficient in practice, because wrong in principle. The ability to pay such a tax would be no guarantee whatever of either ability or respectability. It is true such a tax might prevent the accession to the professional ranks of a few "needy villains," who now find the art a cheap pretext for their nefarious practices; but in regard to many of those already in existence, the more unscrupulous they may be, the better they can afford to pay for the permission to practise. We have repeatedly suggested the great advantages which might be derived from the existence of a photographic school or college where pupils graduating could acquire a thorough knowledge of the chemistry, art principles, and manipulatory details of every branch of photography. Such a college, might confer degrees and grant diplomas, which should be a guarantee to the public of the ability of those possessing them, and thus afford an effectual protection from the necessity of dealing with bunglers. In the absence of such a college, we can conceive that a society might be established with power, if not to impart instruction, at least to institute examinations and grant certificates of merit, which it might be an object of ambition to aspire to. Other methods might be suggested by which the honourable and skilful practice of the profession might be protected. Any scheme which guaranteed increased culture in the profession would receive our hearty approval. But the mere establishment of a prohibitory tax we should regard as wrong in principle, and inefficient and irksome in practice, and we should feel it our duty to give it our unhesitating opposition.

The proposition of W. B. N., in another page, to establish a penny patent, or copyright, for photographs, is more plausible. Our correspondent proposes that a penny adhesive stamp should be prepared for affixing to photographs, a copyright in which is desired, and that it be felony to copy any photograph to which such stamp shall be attached. We almost fear that if this proposition come under the attention of the Chancellor of the Exchequer, it will be suggestive of a source of revenue too tempting to be neglected. When we contemplate the hundreds of thousands of album portraits which are now published and sold, we feel assured that a very large revenue might be derived from such a tax. We are not, however, sufficiently patriotic to see it put in operation. We object to it on principle. There is an implied contract at all times between a Government and the people, which binds the former to protect the property of the latter. One purpose of the revenue derived from the ordinary sources of taxation is the administration of those laws which protect property. We object, therefore, to the notion of photographers paying an especial tax for the protection of their property. The picture of whatever subjects a photoprapher may produce, costs him something, and becomes his property; and we hold it a duty of the state to protect that property, without the payment of any especial fee beyond what he pays in common with his fellow-citizens. Class taxation is opposed to the whole spirit of the age; and a tax upon anything contributing to the elevation and cultivation of taste, as photography does, would be most odious.

Photographs merely claim from the Government the same protection which is now awarded to similar property, a copyright, such as is possessed by pictures and books. In the Bill brought before the House by the Attorney-General during the last session of Parliament, for improving the law of copyright in works of fine art, a recognition of the claims of photography was made. Photographs were classed amongst pictures, and negatives were placed in the same category as copper and steel-plates. The Bill will be doubtless brought before the House again next session. If photographers are concerned to protect their productions, let them exert themselves by bringing as much of the "pressure from without" as possible to bear upon Parliament. Let those who have influence with members, use that influence to secure their support in the House, and let all interested in the matter show their interest when the time comes by petitioning.

The further suggestion of W. B. N. as to rendering the possession of a licence necessary to all travelling-photographers, perhaps possesses more justice. It has generally been recognised that those classes who escape the ordinary taxation, falling upon persons with a fixed residence, should pay some equivalent, for the possession of a hawking-licence. How far the number of photographic hawkers renders the question one of importance; or how far the strict administration of existing laws would bring travelling photographers within their operations, we cannot offer an opinion.

THE ART CLAIMS OF PHOTOGRAPHY.

We may very well leave this question for the present with the exhaustive consideration it has received. Before entirely quitting the subject, however, we cannot forbear making brief allusion to the recently published letter of M. Silvy, in reply to the first letter of M. Claudet, which appeared in the society's journal. As our readers are aware, at the outset of the misunderstanding which occurred between her Majesty's Commissioners and the society, M. Silvy addressed a letter to the Council of the society, stating that whatever decision might be come to by the Commissioners, he should demand admission for his productions into the mechanical department, and affirming emphatically the essentially mechanical character of his art. M. Claudet commented in forcible terms upon the singular position thus claimed, and the reasons by which it was supported. M. Silvy now replies to M. Claudet in a courteous and well written letter, ostensibly defending his former position, but in reality yielding the whole question in dispute. He says:—

"I accepted the department which the Royal Commissioners had given to photography (that is to say, the mechanical one). You find the position assigned to photography unworthy of it; you protest, and demand for it a classification with the Fine Arts. Let us, then, examine frankly and calmly, if you will, the subject in dispute. I also assert that photography is worthy of occupying in art an elevated rank. I also assert that this art requires not only mechanical aid (which is the fundamental basis), but also thought, taste, judgment, and tact; but I imagine that if, for that reason, it holds position amongst the arts, it has not one amongst those properly called the Fine Arts.

"All your arguments prove that photography is an art. Irrespective of the excellence of the machines and accessories, the artist who practises it must, to merit that name, prove his talent, ability, taste, and sentiment; but there is one quality which you do not cite, because, in fact, it is not indispensable to photography, that is to say, Genius, the genius which invents, creates, composes, and which imprints on its works the immortal seal of the Fine Arts. Fine amongst all arts. This distinction is not new. The ancients recognized it. It is from them that it comes. The Greeks, more than any other people, animated with the sentiment of the beautiful (a sentiment elevated amongst them to a religious rite), personified the Fine Arts under the symbolical figure of Apollo, who combined all:—

Appollo, God of the Fine Arts,
Whose forehead shines as the Home of Genius,
Whose lips open not but for the sublime songs of poetry,
Whose fingers draw from the lyre melodious sounds or stamp of the marble the expression of his thought.

"Ages have passed, and the Fine Arts ever flourish with the same brilliancy. Poetry and literature, music, sculpture, painting, and architecture, are alone the Fine Arts. Every other, according to its nature, is divided into liberal, mechanical, or industrial arts, &c. These have acquired in our time sufficient importance that no one can blush at being classified among them. Besides, the classification exists from time immemorial; have you sufficient pretensions to overthrow it? You are, you say, something more than a mere machine; you have, moreover, talent, taste, mind, feeling. I am happy to acknowledge it; but all that fills not up the gulf which separates photography from the Fine Arts. Fine Arts create. Photography copies. The difference between the two is so clear, so evident, that it is unnecessary to dwell on the point. What photographer would be foolish enough to claim a place with Raphael, Michael Angelo, Rubens, and all the glorious names which history has left us?"

If this be not a complete cession of the whole question at issue, it is something very like it. Photography is art, but it is not *fine* art, because it "copies" and does not "create." Thus the art that copies is not fine art. Alas, then, for Apelles when he painted Alexander! He copied what he saw, he did not create. Alas for a large proportion of the productions of the great masters from his time downwards! Alas for Vandyke and Holbein, Sir Peter Lely and Sir Godfrey Kneller, Sir Joshua Reynolds and Sir Thomas Lawrence, and a host of others, who, like them, have been chiefly portrait painters. They have copied, not created. Alas for some of the most distinguished names enrolled in the Royal Academy of this day, they are portraitists: they copy, not create!

But since M. Silvy makes the claim of photography to rank as a fine art rest on this distinction, have we not a right to press him a little closer for definitions? What is creation in painting? If we accept Locke as our guide in philosophy, and repudiate the notion of innate ideas, every painting must be a copy of something. It may be a combination of many things, but all its parts must have been copied from something. If all the ideas in the mind are the result of impressions from without, then this creation is but combined copying. But this is bordering too closely on the region of metaphysics, and we will not pursue the argument.

If M. Silvy's definition as to the right application of the term "fine" to art be correct, then painting and sculpture both, so far as they are "imitative" or "copying" arts cease to be fine arts, and section IV of the International Exhibition would almost cease to have an existence. It is quite clear that such a distinction is altogether inadmissible, and would be unhesitatingly repudiated by those who already hold an undisputed position in the fine-art circle. The fact is, M. Silvy does himself injustice. The pictures of few photographers have higher art claims than his, and it is but the pride of humility on the part of the artist, to rate them as mechanical productions.

The position of photography has yet to be recognized. The story related some time ago, in a contemporary, is so apt an illustration of the case, that it might have been coined for the occasion. When the letter of M. Silvy was received by the Council of the Photographic Society, the president, it is stated, asked, "Who is Silvy?" M. Silvy, as it is well known, is one of the most talented and successful photographers of the day; but he is young, too young, and too recently established, to be known and recognized by an august conservative tribunal. Photography, one of the most wondrous discoveries of the age, has achieved the most brilliant results, and made the most astounding progress. But it is young—too young to be recognized by constituted authorities as an equal amongst the fine and graphic arts. Our correspondent, R. A., now practically assumes that position. He does not even doubt the capabilities of the art; he merely denies that it has yet made good its fine-art claims.

Well, all this simply constitutes a public challenge to photographers to make good the claims of their art. Her Majesty's Commissioners, we are assured, do not, in assigning to photography the position they have done, assume the position of a tribunal; they merely accept things as they find them. Photography has not yet received recognition amongst art authorities as a fine art. Once more, then, we urge upon photographers to make such a display at the forthcoming Exhibition, as shall set the question at rest, once, and for ever.

Scientific Gossip.

Whether the actual change undergone by chloride of silver upon exposure to light is as simple as some persons imagine, there may good reasons to doubt. The subject is one of great difficulty to decide one way or another, and several of the phenomena noticeable when the discoloured chloride is treated with reagents will admit of equally clear interpretation according to two or three different theories. One of the most recent writers on this point with whom we have recently become acquainted is the great Dutch chemist, Mulder. In a very elaborate research on the various phenomena connected with the formation of chloride of silver by precipitation (on which apparently hacknied subject he has written a good sized volume, full of interest and novelty) this experimentalist has given a very excellent resumé of the extent of our knowledge of this valuable photographic chemical, and has contributed a vast number of new facts which tend to clear up certain obscure points of its history. The well-known chloride of silver, as ordinarily precipitated by hydrochloric acid or a soluble chloride from a solution of nitrate of silver, is a very spongy precipitate; indeed, there are few chemical compounds like it in this respect. It appears as flocks, the particles of which retain their coherence even after strong agitation of the liquid in which they float about, and they even resume that coherence if it has been momentarily disturbed by stirring the liquid. The smaller particles of the precipitate, which float about in the liquid, are taken up in that spongy mass more or less in the same way that the flocks of albumen render clear a turbid liquid. An application of heat produces movement in the liquid, and whatever produces motion brings the smaller particles in contact with the more flocculent ones, whereby, while the liquid is rendered clear, the smaller particles are taken up by the larger. The liquid, after shaking, does not, however, at first become perfectly clear; it is even optional with the operator to render it more or less clear as he may desire. If, after the addition of common salt to the silver salt, some of the latter is still left unprecipitated, a more coarsely flocculent precipitate is obtained; if now a fresh portion of the solution of common salt is added and the liquid briskly shaken, the first-formed large flocks take up very readily the large number of smaller particles of chloride of silver produced by the second addition of common salt, and the liquid isrendered perfectly clear.

Chloride of silver is soon discoloured by light, being rendered violet coloured and heavy, whilst some chlorine is set free. According to Pohl, chloride of silver, which is precipitated at a temperature of from 60° to 80° C., is not discoloured by light for many days if it remains under the surface of the liquid, kept at the same temperature. The same writer states that the discoloured chloride of silver becomes, under the same circumstances, somewhat more white.

The existence of a subchloride, Ag_2 Cl, is assumed by Wittstein in the discoloured chloride of silver; he affirms that it is not attacked by nitric acid, and that it is decomposed by ammonia into chloride of silver, which is dissolved therein, and into metallic silver, which remains undissolved. In reference to this, Dumas says that the quantity of subchloride which gets formed in this decomposition is very small, and the quantity of chlorine set free very small also. Rose even goes so far as to assert that it is impossible to find any difference in the weight of the white and discoloured chloride of silver, when even a very sensitive balance is used. This statement is, however, disproved by Mulder in the following experiment. A quantity of pure silver, weighing exactly one gramme, was dissolved in nitric acid, and precipitated by a solution of common salt, added in precisely sufficient quantity to obtain the point of chemical neutrality —there being, therefore, neither excess of silver, nor of chlorine. The bottle containing the precipitate was exposed to light, and sufficiently shaken from time to time to discolour as much as possible the particles of chloride of silver. Upon testing the supernatant liquid for chlorine, Mulder found in it as much as would unite with 6·25 milligrames of silver. Now since 1 gramme of silver forms 1·33 grammes of chloride of silver, the 6·25 milligrammes of silver required to saturate the chlorine set free in this experiment, represent 2·06 milligrammes of chlorine. In case the whole of the chloride of silver had been converted into subchloride of silver, the half of 0·33 gramme of chlorine, that is 0·165 gramme should have been set free, whereas in this experiment only 1-83rd of the whole of the chlorine present had been set free, showing that the decomposition, even under the most favourable circumstances, is very slight. Enough chlorine, however, is evolved to be easily detected by a chemical balance, as in the above experiment it amounts to 2·06 milligrammes; and chemists are in the constant habit of weighing to a tenth of that amount.

Mulder states it as his opinion, that the violet coloured matter formed, when chloride of silver is exposed to light, is a mixture; part of it is perfectly soluble in liquid ammonia, while another part of it gets decomposed by ammonia, of which part again is rendered insoluble, the latter being metallic silver.

Chloride of silver which had been precipitated from a solution of nitrate of silver by means of common salt, and which had been exposed for some time to daylight was carefully freed from the supernataut liquid, and liquid ammonia was poured over it. Nearly all was dissolved, a small portion only remaining insoluble after having been in contact with excess of the alkaliue liquid. This small portion exhibited the same colour as the powder of minutely divided silver, as it is separated for instance by precipitation by formic acid: it did not possess any violet tinge, and therefore the violet colour of discoloured chloride of silver cannot be attributed to this substance. The metallic particles, insoluble in liquid ammonia, are exceedingly minute, few of them being of sufficient size to be retained by a filter. They are soluble in nitric acid, (the violet chloride it will be remembered is insoluble in this acid,) and the solution is precipitated by common salt; these insoluble particles are therefore metallic silver.

The solution of violet chloride of silver in ammonia gives rise, besides these particles of metallic silver, to a colourless liquid, which being supersaturated with nitric acid, yields again pure white chloride of silver, all the violet colour being gone. The following is Mulder's explanation of these phenomena:—The chloride of silver, AgCl, is reduced in small portion, by daylight, to the state of subchloride, Ag_2Cl, which has a violet colour, chlorine being set free. If to this subchloride, Ag_2Cl, ammonia is added, it then yields a colourless solution of chloride of silver, AgCl, the other portion of Ag being left behind in the form of an insoluble powder. Even on being warmed with it, nitric acid does not change violet-coloured chloride of silver to white; chlorine water, however, produces this effect instantly. The reason why chloride of silver which is so readily changed by daylight into subchloride, is not totally changed iuto it, is entirely due to the chlorine which is set free. An excess of chlorine is au impediment to the formation of the violet material.

Such in a few words is Mulder's view of the interesting and important reaction which takes place in chloride of silver when under the influence of light. Coming from so eminent a man, these opinions are deserving of every attention; but it must not be forgotten that experienced chemists in our own country, have given it as their deliberate opinion that the theory of the existence of subchloride of silver has been assumed upon insufficient grounds, and that all the hitherto observed phenomena produced by the action of reagents upon the discoloured chloride of silver can be equally well explained upon the assumption that the action of light upon the chloride of silver is simply to split it up into its two elements, silver and chlorine. Spiller's experiments on this subject, executed with his well kuown care aud acumen, appear decidedly to favour the latter view of the decomposition.

CHLORIC ACID IN THE NITRATE OF SILVER BATH.

BY M. MC. A. GAUDIN.

For a nitrate of silver bath to act well with all kinds of developing agents, it must be acid, but only in the slightest degree possible. I have previously shown that the acids at present employed, acetic aud nitric, yield variable results, which are due to their volatility and to their decomposition in presence of the ether compounds which are formed in the silver bath by the action of a high temperature. It is this fact which has induced me to employ a fixed and stable acid which would not, under any circumstances, produce a precipitate.

Under this relation chloric acid occupies the first rank. The chlorates are soluble like the nitrates, and when a silver bath is once properly acidulated with chloric acid, it always retains the same acidity, notwithstanding the concentration of the bath, or even its complete dessication.

Chloric acid is obtained from chlorate of baryta; it is rather costly, but so little of it is required for the purpose here indicated, that the price is no object.

After making a saturated solution of chlorate of baryta, sulphuric acid is added to it so long as a precipitate is formed. This precipitate is sulphate of baryta, and the filtered solution is chloric acid in a state of dilution fit for use.

After preparing a neutral silver bath solution, I employed it for obtaining proofs which came out well with a pyrogallic acid developer more strongly acidulated than usual. Upon the additiou of ten drops *per litre** of chloric acid, the silver bath reddened litmus paper in a very marked degree, and the negatives obtained with the bath thus modified came out well with the same time of exposure. I afterwards increased the quantity of diluted chloric acid, to the extent of five per cent. of the volume of the silver bath. A notable dimiuution of seusibility was the result, but infinitely less than if I had added diluted nitric acid in the same proportion.

The diminution in sensibility appeared to me exactly similar to that produced by acetic acid, and this induces me to say that diluted chloric acid is the best agent for acidifying nitrate of silver bath solution.—*La Lumière.*

Photographic Tourist.

MY FIRST PHOTOGRAPHIC TOUR.†

We rose early, and did what you would call a hard *day's* work before breakfast. Yes, before breakfast, for well do I remember how the gloom of coming night shrouded the town, a tedious hour or more before there was any prospect of that same breakfast making its appearance; nor do I forget how grim despair's sickening and wearying heralds held us in thrall as the misty veils thickened about us, and that first meal still loomed faintly in the distance.

The day in question began, and continued, thus:—In the first place I hung out upon the door-post our unglazed specimen case; thereby attracting a group of indolent loiterers, whose remarks, made in the most audible of stage whispers, were as freely applied to my blushing and uncomfortable self as to my specimens. In the next, I proceeded, with no little nervous trepidation and anxiety, lest all should not go right, to get ready for the much prayed for customers, by cleaning and buffing some plates, &c. Perhaps you never rolled up your shirt sleeves on a hot summer day, and bobbed to and fro, to and fro, for no end of time, over Daguerreotype plates until your wet hands clung to the handles of your "buffs," and tickling, trickling sensations crowded over every half inch of your hotly glowing person. If you never did, why bless collodion for the fact, and subscribe at once, if it be not too late, to the Archer Testimonial Fund.

Victimizing my wife as a sitter, I proceeded to rehearse my part for a first appearance in the character of a Daguerreotypist, in order that any possible influx of patrons might not find me unprepared for their reception. Of course things went wrong, they always do when there is any special and particular reason why they should not do so. I placed my "buffs" out of doors in the sun to keep them warm and dry, forgetting the dust. I had forgotten not only the dust, which was easily brushed off again, but the greasy fingers which might be passed over the scrupulously cleaned leather, just to "feel how smooth it was," when my back was turned. The plate coated unevenly over the iodine. My box containing the "quick," or bromide of lime, had not been made properly air-tight, and the bromine had considerably escaped, so that I found it almost impossible to get any half-tone in the pictures. I forgot to filter the mercury so as to remove the oxidized surface. The thermometer attached to my mercury box had got broken, so that I had no idea of the heat, and the pictures were all "peppered" from excess of mercury; my fingers damp with excitement and perspiration caused stains at the spot where they touched the plate in placing it over the mercury. When I finally got a picture near the mark, my first batch of "gilding" was spoiled by pouring the hypo into the gold instead of the gold into the hypo. Making up some "sel d'or," which I luckily had, I proceeded to gold, or "enamel," as I had been taught to call it, and as I anxiously watched the picture improving in colour and brilliancy, I continued the application of heat until up suddenly flew the surface, cracking and exfoliating. I made one blunder after another, until confused, bewildered, and teazed, past bearing, I sat down in the little dark closet I had extemporised and cried and sobbed like some poor, sick, scolded, heart-broken little child. I could not, despite my utmost care, get such pictures as I could hope would find purchasers, and without such, what on earth could I look forward to? Think of this before you laugh at me, my dear reader.

From this unmanly fit of weakness I was aroused by the glad voice of my exultant little partner, announcing joyously "*Our first customer.*"

Well, perhaps our first customer was not absolutely and perfectly beautiful, observing her red hair, her small, round-tipped, highly polished nose, her slit-like eyes, and her gash-like lipless mouth; any cold, uninterested observer might have called her, I don't doubt, a very vulgar, ugly, talkative, little serving-wench. I called her an angel, a most radiant being, full of *spiritual* beauty!

"Wott'll yer take to do my likeness, mister," said this "radiant being," as, having smoothed my damp, straight hair, and wiped the tears and perspiration from my flushed and burning face, I bowed myself into her glorious presence. After patronizing me to a very liberal extent in promises, and evincing in other ways, the condescending nobility of her nature, she sat for a "five-and-sixpenny" picture, for which she was to call again in an hour or two. I won't say much about the picture I got, it was certainly better than its predecessors, but, well, I hoped it would pass, and waited anxiously for the "radiant being's" second visit; for till her visit and her money had been paid we could but remain foodless.

Now to secure another hope, apart from that of selling the Daguerreotype. I set to work and made a sketch from it in india-ink, and giving this a few washes of colour, succeeded in completing it exactly ten minutes after the second hour had passed and her angel form was due. But three hours passed, and she came not; three hours and a half passed, and still the spiritual beauty of her presence was desired: "Shades of evening close not o'er us" said we, in vain, for they would and did do it, and yet we mourned her absence. Nearly all the the light of our room had gone out of the window, and thick darkness had seized upon its corners, when from the gloom near the door came a voice of music to our eager ears, crying pantingly—

"Oh! lor, arn't I had a run for it, and no mistake, mister!"

We borrowed a light from our landly, for candles we had none. The light of those angelic eye-slits fell upon my Daguerreotype—the voice of music denounced it. Oh! what a sinking of heart was there, my readers. From those slits aforesaid a glance illumined my sketch, the voice of music uttered melodious sounds of praise and pleasure. Then! what a leaping in the breast was there, my readers. And so I won my "breakfast" aud we sat down to partake of it with light and grateful hearts, and going early to bed, slept so long and sound and dreamless a sleep, that it was like a foretaste of our death-slumber.

* A litre is about 35¼ fluid ounces.

† Continued from p. 414.

The next day was market-day, Friday, and my show case, being in Conduit-street, leading to the market-place, was surrounded with numerous admirers immediately it appeared. The clattering of horses' hoofs, the screeching and squeaking of pigs, the rattling of carts, the loud-voiced recognitions and salutations of a crowd of pedestrians, the bleating of sheep and the lowing of cattle, &c. &c., made this day a strange contrast to its predecessor, when the street was so quiet and deserted that I feared my presence in the town would not be generally known in much less than two years, if I depended for its announcement upon the exhibition of my specimen case. It turned out quite a bustling busy day with me too, for ere it closed, I had taken and finished no less than eight pictures, all more or less satisfactory; of a farmer with blue coat and brass buttons, cord breeches, top boots, and a broad brimmed fluffy beaver hat, of two farmers in all the fashionable grandeur and style, and with all that haughty supercilious air too, of Regent-street fops, of another farmer in a loose frock-coat, the tails of which flapped playfully against his heels; of another fat old farmer who fell asleep before I could uncap the lens, of two farmers' daughters whose lofty air of condescending superiority highly befitted their aristocratic pretensions, and who drove off in a cart with two small porkers; and of one farmer's wife, who promised that on the next market day no end of other farmers, and farmers' wives, and farmers' daughters, should patronise R. A S.'s Chelmsford "establishment," IF *her portrait "turned out a good one."*

For the remainder of that week we were unvisited and alone. At the beginning of the next I made a step upward in the esteem of my neighbours, being visited by one of the awfully mighty ones of Chelmsford; the great ———, who lived in a large stately house standing in the London road, but which house was somewhat like ———'s person and character, more wide in surface than great in depth. This last remark, however, may arise from prejudice, for I did not please him, and I did displease him.

Soon after we were again penniless, and in despair, so I sat down and exhausted our supply of note-paper and envelopes by writing certain circulars, which set forth how, R. A. S. "having achieved a London reputation" (heaven forgive me for lying) was "making a short stay," &c. &c., and these circulars we ourselves delivered at the doors of the more respectable-looking houses. The effort produced nothing. We passed a day without food, when it struck me that by personally exhibiting a few specimens at some houses outside the town I might perchance get something to do "at their own houses." Accordingly off I started, empty and melancholy, on my errand. Several times I advanced as far as garden gates, and found my courage ooze away before I could open, them. At last seeing a lady in a garden I made a desperate effort and began to address her, but, I suppose the desperation of the attempt found expression in my face, for no sooner did I open my lips than the lady cried hurriedly, "Oh dear no!" and retreated with evident affright into her house, not only shutting, but, as my ears informed me, rapidly bolting the door also. My next application was more successful: a kindly, venerable old quaker lady listened to me with a pleasant smile full of encouragement, and bade me come and "take" her little boy on the morrow, in water colours.

In the morning I went, sat down in the cheerful dame's neat and cleanly little parlor, finished my sketch, received its price and a glass of home-made ale. and bade my patron adieu. My wife met me on the road, anxious to hear how I had fared. I exultingly showed her the money: we purchased food on our way home, and ate it directly afterwards.

In a day or two we were as badly off as ever, and no new chance seemed likely to save us from starvation, when—Oh! jubilee!—a letter from London informed me that a picture painted and left with a dealer before I started had sold for £20, a cheque for which—short the amount of commission—was duly enclosed. R. A. S.

PHOTOGRAPHIC PORTRAITURE.

BY M. DE VALICOURT.

It is most important that exposure should follow the preparation of the glass-plate, for if it be delayed too long, the collodion film, already partially dried, will lose a great portion of its sensibility. The operator will therefore take care to have everything ready beforehand; the pose to be given to the model, the focussing, and all the other preliminaries of exposure, so that at the last moment nothing remains to be done except to take a rapid survey of the preparations. It will be prudent to allow no more than two or three minutes to elapse between the sensitizing of the plate and its exposure in the camera.

The time of exposure is governed by a crowd of circumstances, the principal of which are, the greater or lesser intensity of the light, the length of the focus of the lens, the greater or lesser distance of the model from the lens, the photogenic quality of its colours, and the comparative rapidity of the collodion. All these elements must be taken into consideration upon determining the time of exposure. Nevertheless we must not forget that the collodion process is perhaps the most rapid of all those employed in photography. With this fact in view, and taking into consideration all the varying circumstances mentioned above, we may fix the extreme limits of exposure between two and sixty seconds. Doubtless a very wide margin exists between these extremes, which must be left to the discretion of the operator, but a little experience will soon enable him to attain the precise point: it is better, however, to err on the side of excess of exposure.

A good negative always presents a slightly solarized aspect when viewed by reflected light; viewed as a transparency, the darkest portions of the image should be of a brown rather than of a blue hue.

An incomplete negative, on the contrary, betrays itself as a very fine positive when viewed by reflected light; but as a transparency, the dark portions of the image are weak, grey, without vigour, or half tones, and yet there exists a harsh contrast as a whole between the lights and darks.

A negative upon albumen must never present the same intensity of tone as one upon collodion. We insist upon this point, to prevent operators falling into error, from being accustomed to operate solely upon collodion. When it is remembered that a negative upon collodion can never be too vigorous, provided always, that a proper gradation of tone exists, for we must always take care to avoid harsh and crude contrasts. This latter condition fulfilled, the best negative will always be that, which, allowing the light to pass through with difficulty, requires for the complete production of the positive proofs, a comparatively lengthy exposure. The image produced by such a negative will exhibit great harmony and gradation of tone: it will exhibit the minutest details in the half tones and shadows without hardness, and, in a word, realize all the conditions which, by assuring success, will decide the reputation of a photographic artist.

The collodion process is almost exclusively reserved for the production of portraits, and it will not be a work of supererogation, to indicate the conditions indispensable for success in this attractive branch of the art.

The artistic value of photographic portraits.—If photographic portraits have their enthusiastic admirers, they have also obstinate detractors. These latter. among which it must be admitted many artists were for a long time included, persisted in regarding a photograph as the product of mechanical intelligence, the measured and cold regularity of whose operations compelled a result which might be anticipated beforehand. They classed the camera with the barrel organ which spins out melody by the turning of a crank. If the practice of photography were confided only to a certain class of mechanical operators, it would, doubtless, merit all the reproaches cast upon it; but, fortunately, the labours of others possessing a true feeling for art, combined with a high degree of manipulatory skill, have brought photography to occupy a high position among the fine arts. Portraits are daily produced, which may vie in every artistic feature with the finest productions of engravers; and if we reflect that every photographer, if endowed with true artistic taste and feeling, can impress a stamp of originality on his works, which utterly precludes the possibility of their being mistaken for the works of another, we shall be compelled to admit that, if photography be a manufacture, it is also an art. Doubtless, *chefs d'œuvre* are the exception rather than the rule, but the public does not, as a general rule, demand works of the highest class; and while content with much that must be ranked as mediocre, it gives an impulse and support to a profitable industry. But even productions of this class take a much higher rank in the scale of art than the crude attempts at miniature painting which they have superseded. Public taste is evidently improving, and by the time that photography is capable of supplying the demand for works of the highest class, we may expect public taste to have made such progress as to tolerate no longer works of inferior merit.

British Association for the Advancement of Science.

PHOTOGRAPHIC SPECTRA OF THE ELECTRIC LIGHT.

BY PROFESSOR MILLER.*

A LECTURE on the subject of spectrum analysis generally was delivered in the Free Trade Hall on Friday evening, but as it consisted chiefly of a historical recapitulation of the facts with which our readers been have from time to time made familiar, it is unnecessary to give any details of the lecture here. The details on the spectra of various electric lights will be interesting:—

"The apparatus by which the spectra may be photographed consists of an ordinary camera-obscura attached to the end of a long wooden tube, which opens into a cylindrical box, within which is a prism glass, or a hollow prism filled with bisulphide of carbon. If the prism be so adjusted as to throw the solar rays, reflected from a heliostat upon the screen of the camera, and the wires which transmit the sparks from Ruhmkoffer coil, are placed in front of the uncovered portion of the slit, the two spectra are simultaneously impressed. The solar beam is easily intercepted at the proper time by means of a small screen, and the electric-spectrum is allowed to continue its action for two or three, or six minutes, as may be necessary. He did not find that anything was gained in distinctness by interposing a lens of short focus between the slit and the wire which supplied the sparks, with the view of rendering the rays of the electric light parallel like those of the sun, owing to the absorbent action of the glass weakening the photographic effect; and the flickering motion of the sparks being magnified by the lens, rendered the lines less distinct than when the lens was not used. Although with each of the metals (including platinum, gold, silver, copper, zinc, alumnium, magnesium, iron), when the spark was taken in air, he obtained decided photographs, it appeared that in each case the impressed spectrum was very nearly the same, proving that few of the lines produced were those which were characteristic of the metal. The peculiar lines of the metal seemed chiefly to be confined to the visible portion of the spectrum, and these had little or no photographic power. This was singularly exemplified by repeating the experiment upon the same metal in air, and in a continuous current of pure hydrogen. Iron, for example, gave, in hydrogen, a spectrum in which a bright orange and a strong green band were visible, besides a few faint lines in the blue part of the spectrum. Although the light produced by the action of the coil was allowed to fall for ten minutes upon a sensitive collodion surface, scarcely a trace of any action was procured; whilst, in five minutes, in the air, a powerful impression of numerous bands was obtained.

"It was remarked by Mr. Talbot that, in the spectra of coloured flames, the nature of the acid did not influence the position of the bright lines of the spectrum, which he found was dependent upon the metal employed, and this remark had been confirmed by all subsequent observers. But the case was very different in the absorption bands produced by the vapours of coloured bodies,—there the nature of both constituents of the compound was essentially connected with the production of absorptive bands. Chlorine, combined with hydrogen, gave no bands by absorption in any moderate thickness. Chlorous acid and peroxide of chlorine both produced the same set of bands, while hypochlorous acid, although a strongly coloured vapour and containing the same elements, oxygen and chlorine, produced no absorption bands. Again, the brownish red vapour of perchloride of iron produced no absorptive bands; but when converted into vapour in a flame, this gave out bands independent of the form in which it occurred combined.

"These anomalies appeared to admit of an easy explanation of the supposition that, in any case, the compound is decomposed in flame, either simply by the high temperature, just as water is, as shown by Grene, or, in all other cases of the production of bright lines by the introduction of a metallic salt into a flame of burning bodies (as shown by Deville). In the voltaic pile the decomposition must of necessity take place by electric action. The compound gases, protoxide and binexide of nitrogen, gave, when electrified, the same series of bright bands (as Plücker had shown), which their constituents when combined furnish. Aqueous vapour always gives the bright lines due to hydrogen and hydrochloric acid, the mixed system of lines, which could be produced by hydrogen and chlorine, The reducing influence of the hydrogen and other combustible constituents of the burning body would decompose the salt, liberating the metal, which would immediately become exidised or carried off in the ascending current.

"There was obviously a marked difference between the effect of intense ignition upon most of the metallic and the non-metallic bodies. The observation of Plücker upon the spectra of iodine, bromine, and chlorine, shows that they give, when ignited, a very different series of bands to those which they furnished by absorption, as Dr. Gladstone had already pointed out; but it was interesting to remark that in the case of hydrogen, which, chemically, was so similar to metal, we have a comparatively simple spectrum, in which the three principal bright lines correspond to Fraunhofer's dark lines, C. F. and G. It was, however, to be specially noted that the hydrogen occasioned no perceptible absorption bands at ordinary temperatures in such thickness as we could command in our experiments, and the vapour of boiling mercury was also destitute of any absorptive action, although when ignited by the electric spark, it gave a characteristic and brilliant series of dark bands.

"The following experiment suggested itself as a direct test of Kirchoff's theory. Two gas-burners, into which were introduced chloride of sodium on the wick of the spirit lamp, were placed so as to illuminate equally the opposite sides of a sheet of paper partially greased, The rays of the electric light screened from the photometric surface, suitably protected, were made to traverse one of the flames. If the yellow rays of the light were absorbed by the sodium flame, the light emitted laterally by the flame should be sensibly increased. The experiment, however, failed to indicate any such increase in the brilliancy of the flame, possibly because the eye was not sufficiently sensitive to detect the slight difference which was to be expected."

ON LIGHTNING FIGURES.

Mr. Tomlinson, of King's College, read a paper on this subject, chiefly with reference to those tree-like or ramified figures sometimes found on the bodies of men and animals that have been struck by lightning. Professor Pocy has collected a number of such cases into a memoir, entitled "The Photographic Effects of Lightning," a second edition of which has been published at Paris during the present year. One of these cases is the following:—A boy climbed a tree to steal a bird's-nest; the tree was struck by lightning, and the boy thrown to the ground; on his breast the image of the tree, with the bird and nest on one of its branches appeared very plain. Mr. Tomlinson explains such cases by referring to breath-figures, and showed that when the discharge of a Leyden jar is received on a pane of glass, it burns away a portion of the organic film which covers all matter exposed to the air, so that when breathed upon, the

* Read on Friday, September 6th, in Section B.

moisture condenses in unbroken streams along the lines where the electricity has passed; while on the other parts of the surface the moisture condenses in minute globules, so that on holding the glass up to the light the figure is distinctly seen, so long as the breath remains on the plate. This figure resembles a tree, bare of leaves, and might (as the President of the Section afterwards remarked with reference to the diagrams exhibited), be taken for any tree in the world. In this figure we have a broad and somewhat rippled line of least resistance or path of the principal discharge, branching off from which are numerous ramifications, from each of which proceed large twigs, and from these smaller ones of great delicacy and beauty. It can be proved that when the discharge of a Leyden jar is thus received on glass, the jar sends out feelers in all directions to prepare the way for the line of least resistance, and this being accurately marked out, the principal discharge takes place. In some cases the discharge bifurcates, and even trifurcates. If the glass presents too much resistance, the breath-figure consists of three feelers only, and these are the lines which produce the sensation of cobwebs being drawn over the face, which seamen sometimes describe as the forerunners of the ship being struck. The main trunk is hollow, and resembles in its structure the silicious tubes known as fulgurites. Mr. Tomlinson took this figure to be typical of the lightning discharge which strikes terrestrial objects, and objected to the stereotyped zigzag by which a stroke of lightning is generally represented. His theory is, that when a tree-like impression is found on the body of a man or animal struck by lightning, a portion of the fiery hand of the lightning itself has passed over the victim and left its mark. Several cases of this kind were described and discussed, but allowance must be made for the imagination of by-standers, which leads them to see in these ramified impressions "an exact portrait of the tree;" the blotches are taken for leaves, for a bird or bird's-nest, &c., as the case may be. Cases were also examined in which these tree-like impressions were referred by medical men to ecchymosis; other cases in which the impressions of a horse shoe, of a nail, of a metal comb, of coins, &c., were found on the persons of the victims, were explained on the principle of the transfer of metallic particles from one conductor to another, as illustrated by the well known experiment of M. Fusinieri. Mr. Tomlinson rejected the photo-electric theory, by which M. Poey attempted to account for the production of all these figures; and in the discussion which afterwards took place, the Astronomer Royal, Professor Hennessy, and others, were disposed to agree to Mr. Tomlinson's view of the subject.

Dictionary of Photography.*

Reticulation, in collodion, consists in the presence of the dried film of innumerable small cracks or fissures, crossing each other and forming a net-work. It is distinct from what is known as "craping," which consists more properly in the formation of corrugated lines in the direction in which the collodion flowed off the plate; although reticulation not unfrequently follows the drying of the film which had in the first instance only shown a craping tendency. A tendency to reticulation may be produced by a variety of causes, but it rarely is absolutely caused save by the presence of too much water in the solvents. The condition of the pyroxyline may be favourable for its production in two ways. A pyroxyline made at a very low temperature, giving a coarse gelatinous collodion, and flowing with a decidedly crapy structure, will sometimes when dry give a reticulated film, even where the same solvents with a better pyroxyline would have caused no such result. But the same pyroxyline with more anhydrous solvents, especially with a preponderance of ether would not have produced reticulation. A very rotten and powdery pyroxyline, especially if its condition be caused by the action of an alkali, frequently causes a tendency to reticulation, its operation in regard to solvents being similar to that just described. It is important to remark that any kind of collodion has its tendency to reticulation much increased by immersion in the silver bath before it is sufficiently set. This really adds a given quantity of water to the collodion; for, instead of the pores of the collodion closing as the ether and alcohol evaporate, which they do whilst it is kept out of the bath, the ether and alcohol in the bath are simply expelled from the film to give place to a given quantity of water. Another cause which materially tends to cause reticulation is long-continued development. By the operation of long-continued development in an under-exposed picture there is generally an increased surface deposit of silver, which causes unequal contraction and consequent reticulation in drying. If the film have any pre-disposition to this reticulation it is frequently produced by any process of intensification after fixing, especially by the use of bichloride of mercury, and more especially still if hydrochloric acid be used in making the solution. It should be observed, then, that where a collodion shows the tendency to produce a reticulated film, it should be allowed to set thoroughly before immersion in the nitrate bath, and should not be used for processes, involving the accumulation of surface deposit by after intensifying; where these latter methods of strengthening negatives are used, a suitable collodion free from reticulating tendencies should also be used. There is no certain method of improving a collodion possessing these tendencies. The only plan is to adopt the precautions in its use we have indicated, or to mix it with another sample of collodion free from such tendency. The addition of about ten minims of chloroform to each ounce of collodion has been recommended as a cure, but is of uncertain efficacy and only applicable at all in certain cases. It is needless to say that reticulation is fatal to the value of a good negative, and every precaution should be used to prevent its occurrence.

Retouching.—The term retouching is used, in photography, to denote that kind of alteration, or improvement, which a print receives from the pencil of the artist when his pigments are of the same tint as the photograph. The mere "touching out" of slight spots scarcely comes under the term "retouching," which is more generally understood to mean the addition of something wanting in the photograph, either of vigour or detail. At one time, in professional photographic portraiture, retouched prints on plain paper were very common; but as the art has advanced, the production of perfect prints has become more general and retouching has fallen largely into disuse. Where it is necessary to resort to such a method of removing defects, or adding improvements, the tint of the photograph should be carefully imitated by means of sepia, madder brown, Payne's gray, Indian ink, burnt carmine, &c., mixed in proper proportions, and if the print be on albumenized paper, a little gum should be added. The colour should be applied with a somewhat dry pencil, and a little at a time. Where the difference in surface caused is very apparent, the subsequent application of an enamel or encaustic paste, is a great improvement.

Rotten Stone.—A soft stone, chiefly found in Derbyshire, which when reduced to powder, and sifted, is valuable as a polishing agent, and is useful to the photographer in cleaning glass plates.

Rouge, otherwise Colcothar, or red oxide of iron.—A red metallic powder, very useful for various polishing purposes. It is used for giving the final polish in grinding lenses. It should be avoided in cleaning glass plates for photographic purposes, as it is apt to be lodged in the imperceptible interstices of the surface, and cause spots.

Sal-Ammoniac.—The commercial name of chloride of ammonium, which see.

Salt.—A salt always consists of two parts, which parts

* Continued from p. 417.

may themselves be either simple or compound. In one case the chloride of sodium may be taken as a sample, which consists of chlorine and sodium. The second class of salts consists of an acid and a base, of which nitrate of silver is a familiar example, each of the parts being in this case compound; one part consisting of nitrogen and oxygen, and the other part of oxygen and silver, or oxide of silver. By the term salt, is meant, in popular phraseology, chloride of sodium.

Saltpetre.—See nitrate of potash.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, 2nd October, 1861.

Some recently executed instantaneous stereographs of this metropolis, produced by one of your London stereoscopic companies, have been exciting some attention here. They are very fine, and perfectly instantaneous, walking and running figures being impressed on the collodion plate, with foot uplifted, never, in the picture, to be put down. It is somewhat singular that until recently instantaneous photography has not been much practised here. Until Messrs. Ferrier's recent street scenes, instantaneous pictures of Paris were comparatively unknown. It is somewhat siugular in a capital where photographic enterprize, generally, is more active perhaps than in any other part of the world, the initiative in populariziug instautaneous views of its streets should be taken by a foreign firm. I say popularizing, because M. M. Ferrier's pictures being transparencies on glass, cannot circulate amongst the people at large, as can these on paper to which I have referred.

One of the partners in the firm of M. M. Ferrier & Co. has been, I understand, travelling in the northern conntries of Enrope, which have hitherto been comparatively untouched by photographers, and some highly interesting pictures, I believe, may shortly be expected.

M. Augendre has invented a white gunpowder, which is composed of

28 parts of prussiate of potash.
28 parts of sugar.
23 parts of chlorate of potash.

The temperature produced by the deflagration of this compound is only 1,900° C. against 2,993° C. produced by ordinary gunpowder, and yet with a weight which gives only 23,000 cubic centimetres of gas with the old gunpowder, we obtain 43,000 cubic centimetres with the white. Besides, the new powder leaves less solid residuum, only 0·77 of the quantity left by the old powder. But with all this superiority we can hardly expect it to supersede the ordinary gunpowder. Messrs. Bunsen and Schischkoff have endeavoured, in an able report to establish the "*chemical theory of gunpowder.*" They consider that the different elemeuts depend, for a given quantity of gunpowder, on the composition of the residuum, on the quantity of this residue, on the temperature produced by the combustion, on the pressure of the gases generated, and on the theoretical work the gunpowder can perform. They have examined all these elemeuts by the most careful analysis and calculations, the results of which are detailed in their report: they have discovered that the decomposition of gunpowder rests upon facts entirely different from those which serve as the basis of the old theory; they fiud that the temperature of the flame of gunpowder burnt in the air is 2,993° C., and in a close space it is 3,340° C. The tension of the gas in the explosion under the projectile never attains 4,500 atmospheres, much less 50,000 to 100,000, as assumed by Piobert.

M. Melsen shows that a powder theoretically good may be, practically, bad; the imponderable fluids, chiefly heat, contact, pressure, quantity, the nascent state, division, volatility, &c., are so many circumstances capable of modifying reactions, and of reacting upon the dynamic effects of powders of the same chemical composition. Messrs. Bunsen and Schischkoff experimented only with a single sample of gunpowder, and it is probable that if they had employed different varieties in their experiments, they would have found occasion to modify their conclusions. The temperature of the flame of gunpowder is variously stated in numbers varying from 2,993° C, to 4,603° C, in the hands of different experimenters. The question of the theory of gunpowder, it must be admitted, is a very complex one.

Some time ago a cupro-ammonical liquid obtained by the contact of copper with ammonia is presence of atmospheric oxygen was proposed a solvent for gun cotton. M. Peligot has published an iuteresting memoir upon the products which accompany the formation of this liquid, specially treating upon a new colouring material, hydrate of copper, which can replace the pigment known as Sauuders' blue, in its applications to painting, calico-printing, and paper-staining. The process which succeeds best in obtaining a large quantity of the cnpro-ammoniacal solution consists in introducing into large glass vessels of the capacity of 10 to 12 quarts, 15 to 20 grammes of copper, and 60 cubic centimetres of concentrated ammonia. The metal, which comes from the reduction of a salt of copper by iron or zinc is passed over the sides of the glass vessel, so as to adhere under the form of a thin layer. In the course of a few minutes the vessel becomes warm, and filled with thick white fumes which are nitrite of ammonia. When the action appears terminated, the atmosphere of the vessel is changed by means of bellows, and the operation repeated several times. Indepeudently of the blue solution thus obtained, there remains a product insoluble in water and in ammonia of a non-uniform colour, yellow, brown, or olive-green, which is a mixture of the two oxides of copper and of the unattacked metal. By substitutiug ammonia saturated with sal ammoniac for the simple liquor ammonia the reaction is much more vivid: in a few moments all the copper is attacked and completely dissolved. Evaporate to dryness in a porcelain capsule, on a *bain marie*, the blue liquor produced by the simultaneous action of the air and the ammonia upon the copper without the addition of the sal ammoniac: pulverise the residne, and submit it to the action of ammoniacal alcohol (alcohol previonsly saturated with ammoniacal gas); it is then filtered, and upon cooling, needle-like prisms of a beautiful violet colour are deposited, the composition of which is NO^3, Cu O, NH^4 O, HO, and which, heated to 212° Fah. are slowly converted into anhydrous nitrite of copper NO^3, Cu O. In contact with a small quantity of water this nitrite dissolves with great reduction of temperature, a portion of the ammonia becomes free and is disengaged; when this solution is left to spontaneous evaporation, hydrated nitrite of ammonia is obtained and a green crystallized salt, NO^3, 3CuO, NH^4 O. When a large quantity of water is poured into the blue solution furnished directly by the copper, ammonia, and air, or upon the two salts derived from this solution, a precipitate of a beautiful torquoise blne is obtained; this is hydrate of copper. CuO, HO; by calcination it gives 80 to 81·5 per cent. of oxide of copper; the formula requires 81·6. It resists the action of boiling water; it may be heated in a stove to 212° F. without undergoing any alteration; it slowly absorbs carbonic acid from the air without changing colour. It may be prepared economically on a large scale, either by treating a salt of copper dissolved in a large quantity of water with an alkali in excess, to which a slight excess of ammonia is previously added; or by pntting some potassa or soda into a solution of salt of copper, previously mixed with sal ammoniac; or still more simply by adding a great excess of water to a weak ammoniacal solution of nitrate of copper. Concentrated *liquid ammonia* dissolves 7 to 8 per cent. of this hydrate; this solution is certainly the best solvent of cellnlose, and of other substances soluble in M. Schweitzer's reagent. M. Chevreul, who has examined the chromatic power of this hydrate of copper, states that its colour is a pure blue, while that of Saunders' blue (carbonate of copper) is a violet blue.

TAXATION FOR PHOTOGRAPHY.

Dear Sir,—As a subscriber from the first number of the News to the last, I beg the privilege of addressing a few words to my brother readers and the public through the medium of its pages. Having seen so often how willingly you accord space for the purpose of advancing the interests of the art, I beg to submit the following suggestion, having for its object the protection of the photographer, both amateur and professional.

You have often reported instances of the latter suffering to a serious extent, both in reputation and pocket, by the piratical copying of their works, for which, at present, there exists no remedy, nor does it appear we are likely to obtain any, unless as a body we secure it for ourselves. I therefore suggest the following remedy, and think that able financier, the Chancellor of the Exchequer, ought not to overlook its merits in a pecuniary point of view, viz., a penny patent. I trust I shall not be charged with egotism in saying, I believe the idea, which is quite original, to be none the less practical. But how is this to be done? I propose in the following manner:—Let there be a penny adhesive stamp, prepared and sold by all the stamp distributors, or obtainable by post-office order from the chief office, the affixing of which on any photograph shall render it a felony to copy and offer for sale or otherwise dispose of. It is obvious that every one would, for safety sake, be sure to stamp every copy offered for sale, as an unstamped one might be copied without infringing the patent right.

As a further security, every one using these stamps should be compelled, in order to prevent fraud, to write across or deface them by stamping his name thus—

Nightingale's }
Registered. }

The writing or stamping of any copy, without the affixing of the patent stamp, to be fineable, not exceeding 40s. for each copy so represented to be registered or patented. It would not, therefore, be compulsory to stamp any one copy, unless it was represented to be registered or patented. This would be a far cheaper mode to the photographer in general, than copyright, as only so many penny stamps need be used as copies sold, and the more of those, as the saying is, the merrier.

I can fancy now that some will say, "Oh, that's very fine then, I suppose, because one fellow takes a view, good, bad, or indifferent, and puts a stamp on it, every one else is to be stopped from taking the same view." But such is not my wish. My object is to prevent another from reaping the benefit by pirating the results of, to a great many of us, hard and expensively procured negatives, and I conceive the penny patent will effect this. There are ways and means to mark every negative without marring it, and a private mark to distinguish it can be put on the negative, which would be copied into every print, to copy which is to constitute the felony.

I mark a good many of my view negatives with the portrait of a tractable dog, to a copy of any of these views I could, therefore, positively swear, from the position and photograph of the dog; and so on in a great variety of ways might every original picture be marked. Portraits could have the name of the photographer in the darkest part of the background, in such a place that it must form part of the mounted proof, but these negatives are mostly well-marked by the furniture, &c., and need no farther proof of identity.
